8 **Abstract**

9 This study presents a physical mechanism on how low frequency variability of the South  
10 Atlantic Meridional Heat Transport (SAMHT) may influence decadal variability of atmospheric  
11 circulation. A multi-century simulation of a coupled general circulation model is used as basis  
12 for the analysis. The highlight of our findings is that multi-decadal variability of SAMHT plays a  
13 key role in modulating global atmospheric circulation via its influence on interhemispheric  
14 redistributions of momentum, heat, and moisture. Weaker SAMHT at 30°S produces anomalous  
15 ocean heat divergence over the South Atlantic, resulting in negative ocean heat content  
16 anomalies about 15-20 years later. This forces a thermally direct anomalous interhemispheric  
17 Hadley circulation, transporting anomalous atmospheric heat from the Northern Hemisphere  
18 (NH) to the Southern Hemisphere (SH) and moisture from the SH to the NH, thereby modulating  
19 global monsoons. Further analysis shows that anomalous atmospheric eddies transport heat  
20 northward in both hemispheres, producing eddy heat flux convergence (divergence) in the NH  
21 (SH) around 15 - 30°, reinforcing the anomalous Hadley circulation. The effect of eddies on the  
22 NH (SH) poleward of 30° depict heat flux divergence (convergence), which must be balanced by  
23 sinking (rising) motion, consistent with a poleward (equatorward) displacement of the jet stream.

24 This study illustrates that decadal variations of SAMHT could modulate the strength of global  
25 monsoons with 15 - 20 years of lead-time, suggesting that SAMHT is a potential predictor of  
26 global monsoon variability. A similar mechanistic link exists between the North Atlantic  
27 Meridional Heat Transport (NAMHT) at 30°N and global monsoons.

## 47 **1. Introduction**

48           The Atlantic Meridional Overturning Circulation (AMOC) is characterized by northward-  
49 flowing warm water in the upper ocean and a southward compensating flow of cold water at  
50 depth (e.g., Broecker 1991; Lumpkin and Speer 2007). There have been numerous efforts to  
51 understand the role of the AMOC as a potential predictor of decadal climate variability,  
52 motivated partly by its inherent relationship with the North Atlantic sea surface temperature  
53 (SST, e.g., Latif et al. 2006; Corti et al. 2012). Therefore, the majority of efforts to understand  
54 the dynamics of the AMOC and its climate impacts have focused on the North Atlantic. The  
55 mechanism for the North Atlantic multi-decadal SST variability, also known as the Atlantic  
56 Multidecadal Oscillation (AMO, e.g., Enfield et al. 2001), has been shown to be modulated by  
57 AMOC changes (e.g., Latif et al. 2004; Knight et al. 2005; Zhang et al. 2013) and linked to  
58 decadal variability of the North Atlantic Oscillation (NAO, e.g., Sun et al. 2015).

59           Sun et al. (2015) suggested a three-way interaction among the NAO, AMOC and AMO  
60 with the NAO leading the AMO by 15-20 years, while the AMO provides a delayed negative  
61 feedback to the NAO. Latif et al. (2000) also found a similar relationship between decadal  
62 variability of the NAO and North Atlantic SSTs. Drevillon et al. (2001) argued that SST  
63 anomalies over the North Atlantic induce atmospheric stationary waves, which are strengthened  
64 by transient eddies. These studies collectively showed that the AMO influences and also is  
65 influenced by the strength of the AMOC and associated Meridional Heat Transport (MHT)  
66 suggesting a delayed advective oscillation (Lee and Wang 2010).

67           North Atlantic SST anomalies associated with the AMO significantly influence climate  
68 anomalies over North America, West Africa and Europe (e.g., Enfield et al. 2001; Kushmir et al.  
69 2002; Rodwell and Folland 2003; Knight et al. 2006; Zhang and Delworth 2006; Ting et al.

2011; Tung and Zhou 2013; Peings and Magnusdottir 2014). Several studies have suggested that the AMO's impact on climate is largely forced in the low latitudes (e.g., Sutton and Hodson 2005). By modulating the strength and meridional location of the Atlantic Intertropical Convergence Zone (ITCZ), the AMO can force extra-tropical atmospheric stationary waves to influence summertime Western Europe temperature anomalies (Ambrizzi et al. 1995; Cassou et al. 2004; Cassou et al. 2005). Some studies argue that the meridional ITCZ shifts are also linked to sea ice concentrations over the North Atlantic (Chiang and Bitz 2005), fresh water fluxes into the North Atlantic (Stouffer et al. 2006; Zhang and Delwoth 2005) and aerosol-induced heating/cooling over the high latitudes in the northern hemisphere (NH) (e.g., Yoshimori and Broccoli 2008). Kang et al. (2009) proposed that antisymmetric interhemispheric heating in high latitudes linked to AMOC shutdown could control the location of the ITCZ, and that its shift could be related to changes in atmospheric energy transport. Consistently, Frierson et al. (2013) argued that oceanic MHT contributes significantly to the asymmetry in precipitation by transporting heat northward, which moves the tropical rainband and ITCZ northward. Several studies argue for the existence of two stable AMOC states, an "on" and an "off" state, from theoretical arguments (Stommel 1961), modeling studies (Manabe and Stouffer 1988; Lenton et al. 2009; Hawkins et al. 2011), and paleoclimate records (Broecker et al. 1985; Clark et al. 2002). Recent numerical model 21<sup>st</sup> Century projections suggest a considerable weakening of the AMOC (Kriegler et al. 2009; Cheng et al. 2013). Zhang and Delworth (2005) showed that a substantial weakening of the AMOC results in a southward shift of the ITCZ, with a weakening of the Indian and Asian summer monsoons, and an El Niño-like pattern in the southeastern Pacific.

92           As briefly reviewed above, the majority of efforts to understand the dynamics of the  
93 AMOC and its climate impact are focused on the North Atlantic. Recently, the research  
94 community started investigating and assessing the role of the South Atlantic on climate. Direct or  
95 indirect measurements from in-situ observations have shown a wide range of AMOC values at  
96 35°S from -0.24 PW (de las Heras and Schlitzer 1999) to 0.55 PW (Dong et al. 2011) and to  
97 0.94 PW (Saunders and King 1995). The AMOC over the South Atlantic Ocean is unique, in that  
98 it is the only major ocean basin that transports heat from the pole towards the equator (Talley  
99 2003). Recent studies have suggested the possibility of the anomalous AMOC and MHT  
100 originating from the inter-ocean transport from the Indian Ocean (e.g., Biastoch et al. 2009; Lee  
101 et al. 2011).

102           The South Atlantic Ocean is characterized by complex and unique ocean dynamic  
103 processes, which are important to the global distribution of energy. For example, the Malvinas-  
104 Brazil Confluence (Garzoli and Garraffo 1989; Goni et al. 2011) plays a critical role in the  
105 exchange of water masses between the subpolar and the subtropical regions. The Agulhas  
106 leakage, , which is the main balance for the outflow of North Atlantic deep water (Gordon 1985;  
107 Sloyan and Rintoul 2001) has the potential for modifying the long-term AMOC response that  
108 could impact global atmospheric circulation and climate (Weijier et al. 1999; Sloyan and Rintoul  
109 2001; Garzoli and Matano 2011). Dong et al. (2011) pointed out that interannual and longer-term  
110 decadal changes in AMOC and MHT over the South Atlantic are due to advective heat  
111 convergence from inter-basin heat exchange, mainly through the Agulhas leakage. Lee et al.  
112 (2011) showed that this inter-basin heat transport has increased since the 1950s and contributed  
113 to the significant increase in Atlantic Ocean heat content.

114 Here, we present a physical mechanism by which the South Atlantic Meridional Heat  
115 Transport (SAMHT) modulates changes in the atmospheric circulation. Our hypothesis is that  
116 low-frequency variations in SAMHT influence interhemispheric atmospheric heat and moisture  
117 transport through slow changes in the upper ocean heat content of the South Atlantic. Our study  
118 shows that this upper ocean heat content anomaly, linked to meridional heat  
119 convergence/divergence, forces a thermally direct anomalous interhemispheric Hadley  
120 circulation as well as atmospheric eddy-driven circulations in both hemispheres, and thus shifts  
121 the location and strength of the ITCZ and modulates monsoonal circulations.

122 The motivation of this work is to enhance our understanding of the SAMHT and its  
123 potential role in predicting global and regional climate variability. In this work, we show that a  
124 weaker-than-normal SAMHT leads to a strengthening and northward shift of the ITCZ about 15 -  
125 20 years later. This is possible through a modification of the zonal mean atmospheric Hadley  
126 circulation by anomalous negative heat content over the tropical South Atlantic, with potential  
127 implications on the global monsoon circulations. For this, multi-century output from a Coupled  
128 General Circulation Model (CGCM) is analyzed. Basic information about the model is presented  
129 in section 2. Multidecadal variability of the Atlantic Ocean transports is discussed in section 3.  
130 Section 4 discusses the atmospheric response to changes in SAMHT. Section 5 presents the  
131 SAMHT modulation of precipitation and monsoon circulations. Section 6 investigates the  
132 relative roles of SAMHT and the North Atlantic MHT (NAMHT). A summary is presented in  
133 section 7, with discussion of a possible mechanism for multidecadal ocean-atmosphere  
134 interactions. Concluding remarks are presented in section 8.

135

## 136 **2. Data and Coupled Model**

137           The global estimate of precipitation for the period from January 1950 to December 2011  
138 is taken from the Global Precipitation Climatology Centre (GPCC, Becker et al. 2013) on a  $1^\circ$   
139 grid. Estimates for the AMOC and MHT at  $26^\circ\text{N}$  are from direct measurements from the Rapid  
140 Climate Change Meridional overturning Circulation and Heat flux array (RAPID-MOCHA)  
141 observing system (Cunningham et al. 2007). The estimates of the MHT at  $34^\circ\text{S}$  are derived from  
142 expendable bathythermograph (XBTs) and Argo float measurements (Dong et al. 2009, 2014).

143           The CGCM used in this work is the Community Earth System Model (CESM1) from the  
144 National Center for Atmosphere Research (NCAR). This earth system model consists of  
145 atmosphere, land, ocean, glaciers, and sea ice components, all linked by a flux coupler. The  
146 coupler exchanges daily information among the components interactively. The atmospheric  
147 component is the Community Atmosphere Model version 5 (CAM5). It has 30 vertical levels  
148 with horizontal resolution of  $1.25^\circ$  longitude by  $0.94^\circ$  latitude. The dynamical core uses the finite  
149 volume formulation. It employs an improved deep convection scheme by inclusion of sub-grid  
150 convective momentum transport and a more realistic dilution approximation for the calculation  
151 of convective available potential energy (Neale et al. 2008). The ocean model component uses  
152 the Parallel Ocean Program version 2 (POP2) (Danabasoglu et al. 2012). It has a  $1^\circ$  horizontal  
153 resolution with 60 vertical levels. This updated version of POP includes a simplified version of  
154 the near boundary eddy flux parameterization of Ferrari et al. (2008), vertically-varying  
155 isopycnal diffusivity coefficients (Danabasoglu and Marshall 2007), an abyssal tidally-driven  
156 mixing parameterization, modified anisotropic horizontal viscosity coefficients (Jochum et al.  
157 2008), and a modified K-Profile Parameterization with horizontally varying background vertical  
158 diffusivity and viscosity coefficients (Jochum 2009).

159 An extensive evaluation of the ocean component of the model over the South Atlantic  
160 and Southern Ocean was discussed in Weijer et al. (2012). There, they showed that simulated  
161 ocean variability over the southern hemisphere (SH) is dominated by the South Annular Mode,  
162 which is consistent with observations. The model also reproduces the correct characteristics of  
163 the frontal zone associated with the Antarctic Circumpolar Current and the SH inter-basin ocean  
164 exchanges to a reasonable degree. However, the model struggles in representing the correct  
165 location of the Brazil-Malvinas current confluence, which is displaced southward compared to  
166 observations. Also, the Agulhas leakage is too strong, and is zonally oriented compared to  
167 satellite observational estimates.

168 In order to have a robust estimate of the mean climate and variability, we evaluate 1,100  
169 years of pre-industrial simulation using CESM1. More detailed discussions on this model can be  
170 found in Kay et al. (2014). All choices of fields analyzed are from monthly mean model outputs.  
171 Although the model does not show any long-term climate drift, all data are detrended before  
172 analysis. The model run is a pre-industrial simulation with atmospheric composition from 1850,  
173 since we are mainly interested in internal variability in this study.

174

### 175 **3. Results**

#### 176 **a. South Atlantic Meridional Heat Transport**

177 Figure 1 shows the mean ocean MHT in the Atlantic derived from CESM1 and from  
178 various observational and reanalysis products. The mean MHT over the Atlantic Ocean is well  
179 represented in CESM1. Its amplitude is larger than estimates from the European Center for  
180 Medium Range Weather Forecast (ECMWF) and comparable with that derived from the  
181 National Center for Environmental prediction (NCEP) reanalysis (Trenberth et al. 2001).

182 Trenberth et al. (2001) found that ocean MHT estimates from NCEP were in good agreement  
183 with direct ocean measurements and coupled models. In contrast, the ECMWF-derived MHT  
184 estimates are deficient due to problems with changes in the observing system, specifically  
185 satellite data. The mean MHT of 1.18 PW at 26°N from CESM1 is comparable with the 1.33 PW  
186 estimated from the RAPID-MOCHA observing system (Johns et al. 2011). The observational-  
187 based MHT estimate at 34°S (e.g., Dong et al. 2009; Dong et al., 2015) is also well captured by  
188 CESM1. Overall, the MHT over the Atlantic Ocean is well represented by the model.

189 An index for the SAMHT is constructed here by computing the anomalous MHT across  
190 the Atlantic basin at 30°S, where the anomaly is obtained by removing the seasonal cycle of the  
191 transport and any trend that might be present. The SAMHT is further decomposed into the  
192 Ekman and geostrophic components. The Ekman component is estimated using monthly mean  
193 zonal wind stress from CESM1, whereas the geostrophic term is simply taken as the difference  
194 between the total and Ekman component.

195 There are two dominant power spectral peaks at frequencies of about 30 and 60 years in  
196 the simulated MHT (not shown). In general, the power spectrum of SAMHT is dominated by  
197 low frequencies with a red-spectrum structure. The reddening is mostly from the geostrophic  
198 component, where most of the power occurs on multi-decadal timescales. The Ekman component  
199 has power at almost all frequencies, although the 60-year spectral peak is also prominent there.  
200 The multi-decadal frequencies (i.e., periods higher than 11 years) contain about 53% of the total  
201 SAMHT variance. For the Ekman (geostrophic) component, the variance explained by the multi-  
202 decadal frequencies accounts for about 35% (83%) of its total variance. Therefore, it is  
203 appropriate to focus on the low-frequency variability of SAMHT. For this, an 11-year running  
204 average is performed on the interannual anomaly of SAMHT, and shown in Fig. 2 as the time

205 series for each component for the 1,100 model years. Note that the Ekman and geostrophic  
206 components have about the same amplitude as the total SAMHT. Overall, the geostrophic  
207 component explains most of the low-frequency variance of the total SAMHT, consistent with the  
208 spectral peaks mentioned earlier. It is also evident that the geostrophic component tends to  
209 redden the spectrum of the total SAMHT, whereas the Ekman is comprised of higher  
210 frequencies, even after the 11-year running average is applied. The results presented here are  
211 largely independent of the choice of the filtering window used, which ranges from 7 to 15 years.

212 The time series shown in Fig. 2a is used in this work as the basis for studying the  
213 relationships between the SAMHT and global climate variability. Those relationships will be  
214 assessed via composite analyses of the state of the SAMHT. A strong (weak) SAMHT is defined  
215 as periods where SAMHT is one standard deviation above (below) the mean value. Here, a  
216 reliable composite difference (i.e., weak minus strong SAMHT) is built from the large sample  
217 size.

218

## 219 **b. Ocean Transport**

220 Figure 3 shows the mean and composite difference of the ocean meridional overturning  
221 streamfunction for the Atlantic Ocean and the global ocean (positive streamfunction values  
222 indicate clockwise circulations). Recall that the composite difference is defined by weak minus  
223 strong SAMHT and referred to here as anomaly. For the AMOC (Fig.3 top), the simulated  
224 AMOC is dominated by northward flow in the upper 1000 m and a return flow below. The  
225 maximum streamfunction occurs at about 40°N. The anomalous AMOC (Fig. 3a) indicates that a  
226 reduction in SAMHT is accompanied by a significant weakening of the AMOC extending from  
227 the South Atlantic to about 45°N. The weakening in the AMOC peaks in two regions, one at

228 30°S and the other at about 30°N. For the global ocean (Fig. 3b), the largest value of MOC also  
229 occurs at around 40°N at 1000 m depth. The upper 700 m tropical band (30°S to 30°N) is  
230 dominated by the shallow overturning cell with upward flow near the equator, occurring  
231 predominantly in the Pacific Ocean (Klinger and Marotzke 2000; McPhaden and Zhang 2002,  
232 2004). The anomalous overturning circulation of the global ocean is very similar in amplitude  
233 and location to that of the Atlantic, suggesting that the Atlantic basin dominates most of the  
234 anomalies at the multi-decadal timescales presented here.

235

### 236 **c. Oscillatory mechanism**

237 This section presents a possible mechanism by which decadal changes in SAMOC and  
238 associated SAMHT could interplay with atmospheric circulation. For this, we analyze the  
239 composite difference of Atlantic Ocean MHT, heat content (HC), heat content tendency, MHT  
240 divergence, and heat flux as a function of lead-time with respect to SAMHT. Fig. 4a shows the  
241 lead-lag composite difference of Atlantic MHT with respect to weak minus strong SAMHT.  
242 Figs. 4b, c, d and e are similar to Fig. 4a but for the surface-to-700m integrated HC, HC  
243 tendency, MHT divergence, and surface heat flux in the Atlantic Ocean. Several depths ranging  
244 from 200m down to the ocean bottom were tested to conclude that results shown here are largely  
245 independent of the choice of the integration depth for heat content calculation. There is an  
246 oscillatory pattern in the MHT (Fig. 4a) that appears to propagate from the north to the south,  
247 with North Atlantic MHT leading SAMHT by about 10 years. That is, the anomalous negative  
248 SAMHT can be traced back to the North Atlantic. Interestingly, the SAMHT leads the opposite  
249 sign in the North Atlantic MHT by about 15 years. Overall, the oscillatory pattern has a period of  
250 about 50-60 years.

251 By construction of the composite, the SAMHT has the most negative value at 0-lag. This  
252 is associated with a negative tendency of HC from 30°S to the equator (Fig. 4c), which leads the  
253 negative HC anomaly 10 - 20 years later (Fig. 4b). The period during and after the weakest  
254 SAMHT (e.g., 10-20 year lead) are dominated by negative (positive) HC anomaly over the SH  
255 (NH). The relationship between MHT and HC is described by (1). Assuming a perfectly enclosed  
256 basin, the zonally and vertically integrated tendency in the heat content is balanced by MHT  
257 convergence and surface heat fluxes:

$$258 \quad \frac{\partial HC}{\partial t} = -\frac{\partial MHT}{\partial y} + Q_{Net} \quad (1),$$

259 where the first term on the right is the convergence of the MHT. The second term is the net  
260 surface heat flux, the sum of two turbulent (latent and sensible) and two radiative (longwave and  
261 shortwave) components. The results described in Fig. 4 show an oscillatory pattern in HC over  
262 the South Atlantic (i.e., Fig. 4b) in association with SAMHT. The negative HC tendency at 0-  
263 year lag (Fig. 4c) is mainly caused by MHT divergence south of the equator (Fig. 4d). MHT  
264 convergence is balanced by heat content tendency at about 10 years prior to the weakest SAMHT  
265 between 15°N-35°N, leading to positive HC anomaly over most of the North Atlantic at 0-year  
266 lag during the weakest SAMHT. The HC anomaly in the North Atlantic Ocean is explained by  
267 MHT convergence, which is balanced by negative surface heat flux at about 10 years prior to the  
268 weakest SAMHT. The MHT convergence is mostly balanced by positive tendency of HC. The  
269 North Atlantic HC anomaly appears to be modulated by the same physical mechanism explained  
270 for the South Atlantic HC anomaly. This relationship among ocean heat content tendency,  
271 meridional heat transport convergence, and surface heat fluxes produces the meridional  
272 asymmetry in the heat content. Its impact on interhemispheric atmospheric circulation is  
273 discussed next.

274 Anomalous Hadley circulation corresponding to weak minus strong SAMHT is depicted  
275 in Fig. 5 as the vertically integrated mass streamfunction about the equator. Here, the direction of  
276 interhemispheric atmospheric heat transport is proportional to the mass transport with northward  
277 (southward) labeled red (blue). Note that the Atlantic Ocean heat transport (Fig. 4a) and the  
278 global atmospheric heat transport (Fig. 5) are mostly in opposite direction to each other. Prior to  
279 the weakest SAMHT (i.e., 15-lag), the atmospheric heat transport is northward. There is  
280 anomalous positive HC over most of the South Atlantic (Fig. 4b) and negative HC north of  
281 20°N, supporting the northward atmospheric heat transport. This positive meridional gradient in  
282 oceanic HC is consistent with the anomalous Hadley circulation about 15 - 20 years after the  
283 negative SAMHT anomaly (Fig. 5, green line), which transports atmospheric heat southward.  
284 Therefore, the SAMHT leads the atmospheric heat transport response by about 15-20 years.

285 In summary, on decadal timescales, the interhemispheric global atmospheric mass and  
286 heat transports are directly linked to the HC of the tropical Atlantic Ocean, which is modulated  
287 by the SAMHT. The maximum northward atmospheric transport, which occurs ~15 - 20 years  
288 before the peak SAMHT, is forced by the interhemispheric gradient of Atlantic Ocean heat  
289 content (Fig. 4b). The maximum southward atmospheric transport at 0-year lag is mostly due to  
290 the anomalous positive North Atlantic Ocean heat content (maximum at about 15°N) formed by  
291 heat transport convergence 15 - 20 years earlier. Of key emphasis is what occurs after the  
292 minimum in SAMHT (i.e., after 0-year lag). The maximum southward atmospheric transport at  
293 about 15 - 20 years lead (Fig. 5) is forced by a dipole in the Atlantic Ocean heat content, induced  
294 mostly by heat transport divergence over the South Atlantic at 0-year lag. This result suggests  
295 that SAMHT could provide lead-time predictability of the state of the zonal mean atmospheric

296 circulation. For this, the next section will be focused on the 20 years delayed atmospheric  
297 response to the SAMHT anomaly.

298

#### 299 **4. Atmospheric response to SAMHT variability at 20 years lead-time**

300 Before assessing decadal changes in the global atmospheric response as a function of the  
301 SAMHT, we first discuss the global distribution of heat budget for the atmosphere and ocean at  
302 20 years lead-time after the anomalous SAMHT. For this, we use monthly mean radiative fluxes  
303 at the top-of-the-atmosphere (TOA) consisting of net incoming solar radiation and net outgoing  
304 radiation. There is large interhemispheric asymmetry in the distribution of radiative fluxes at  
305 TOA, with the NH receiving a net flux of 0.14 PetaWatts and the SH losing 0.26 PetaWatts.  
306 There should be a net southward heat transport by the combined ocean and atmosphere system,  
307 which is shown by the hemispheric asymmetry of upper-ocean heat content in Fig. 4b. Overall,  
308 there is an interhemispheric difference of about 0.4 PetaWatts in both the ocean and atmosphere  
309 at 20-years lead-time after the anomalous negative SAMHT. This is roughly the same amplitude  
310 as the decadal variability of SAMHT. This asymmetry must be balanced by meridional heat  
311 transport. The composite difference of 500mb temperature, SST and precipitation is shown in  
312 Fig. 6 at 20-year lead-time. There is tropospheric cooling (warming) in the SH (NH) associated  
313 with SST anomalies of the same sign. The largest SST anomaly occurs over the South Atlantic,  
314 consistent with the negative heat content there, as shown in Fig. 4b. Although the SST forcing is  
315 zonally asymmetric, atmospheric eddies and westerlies homogenize it into a symmetric  
316 atmospheric response (Kang et al. 2014). This creates an equatorially asymmetric precipitation  
317 response in the tropics (Fig. 6c), with positive (negative) anomaly in the NH (SH). A study by  
318 Sun et al. (2013) investigated the relationship between the equatorially asymmetric precipitation

319 and inter-hemispheric SST dipole. They found that this SST dipole arises from variability related  
320 to northward cross-equatorial ocean heat transport, with potential influence on decadal variability  
321 of tropical precipitation. The role of atmospheric eddies and the mean circulation is discussed  
322 next.

323 Atmospheric circulation associated with the SAMHT is assessed by analyzing the  
324 composite of the weak minus strong SAMHT, 20 years after the anomalous SAMHT. Here, a  
325 zonal mean approach is adopted to quantify the meridional fluxes of heat and moisture. Fig. 7a  
326 shows the time mean and zonal mean meridional circulation (MMC) of the atmosphere as  
327 measured by the mass streamfunction (contour) and composite difference (color). Figs. 7b and c  
328 are identical to Fig. 7a, but for the meridional heat flux and meridional moisture flux,  
329 respectively. Here, heat flux associated with MMC is defined, as  $[\bar{v}][\bar{T}]$  and moisture flux is  
330  $[\bar{v}][\bar{q}]$  where  $v$  is the meridional wind,  $T$  is the temperature, and  $q$  is the specific humidity. The  
331 over bar represents time mean and brackets represent zonal mean. Northward heat and moisture  
332 flux are indicated by positive contours. The Hadley circulation is a thermally direct circulation  
333 that transports heat by its upper branch (i.e., away from the equator) and moisture by its lower  
334 branch (i.e., towards the equator). The MMC (Fig. 7a) shows anomalous negative streamfunction  
335 around the equator of the order of 10% of the mean circulation. This is indicative of  
336 strengthening (weakening) of the SH (NH) Hadley circulation about 20-years after the  
337 weakening of the SAMHT. Implications for this circulation pattern are highlighted in Figs. 7b  
338 and c in that there are anomalous interhemispheric heat and moisture fluxes (NH-to-SH heat flux  
339 and SH-to-NH moisture flux). Similar to the MMC anomalies, the composite differences in the  
340 heat and moisture fluxes are also both about 10% of the mean fluxes and are located near the  
341 equator. This anomalous circulation pattern implies strengthening of the ITCZ to the north of the

342 equator (e.g., 15°N) where moisture flux convergences at lower levels and heat flux divergence  
343 at upper levels increase the Convective Available Potential Energy (CAPE) and thus strengthen  
344 the NH summer monsoon via the so-called interhemispheric teleconnection mechanism (e.g., Lee  
345 et al. 2013).

346         The MMC is well known to be crucial in heat and moisture distribution from equator to  
347 higher latitudes. However, atmospheric eddies, stationary and transient, are also important in  
348 heat distribution at mid-latitudes. In a zonal mean state, stationary and transient eddy heat flux is  
349 toward the poles. These eddies result from the unstable equator-to-pole radiative-convective  
350 equilibrium temperature gradient. Besides the poleward heat transport, eddies are important in  
351 transporting angular momentum poleward, which maintains the easterly winds in the tropics and  
352 westerlies in mid-latitudes. Similar to Fig. 7, Fig. 8a depicts the 500mb mean transient eddy heat  
353 flux (black) and composite difference (green) corresponding to the weak minus strong SAMHT  
354 at 20-year lead-time. Transient eddy flux is defined as  $[\overline{v'T'}]$  - the product between meridional  
355 wind and temperature anomalies. The primes indicate anomalies, defined by the departure of the  
356 daily data from its monthly mean. Positive heat flux indicates northward flux. The anomalous  
357 heat flux is about 10% of the total heat flux. The total heat flux is stronger between 45° and 60°  
358 in both hemispheres. This is typically the location of the maximum momentum flux  
359 convergences, and hence the location of the maximum zonal wind. The anomalous heat flux  
360 (green line) is negative and equatorward (i.e., 30°) from the location of the strongest mean heat  
361 flux in both hemispheres. This suggests a poleward (equatorward) shift in the NH (SH) storm  
362 track or the mean location of the mid-latitude transient eddies. As a consequence, the anomalous  
363 transient eddy heat flux works to cool (warm) the mid-latitudes in the NH (SH), indicating heat  
364 flux divergence (convergence). That is, eddies work to reduce the anomalous temperature shown

365 in Fig. 6a. Eddy heat flux convergence must be balanced by ascending motion (red region in Fig.  
366 8a). Similarly, eddy heat flux divergence must be balanced by subsidence motion (blue region in  
367 Fig. 8a).

368 The zonal mean stationary eddy heat flux and composite difference are shown in Fig. 8b.  
369 Stationary eddy fluxes are defined as  $[\overline{v^*T^*}]$ , where the stars indicate deviation from zonal mean.  
370 The strongest heat flux occurs at upper levels and near the surface. The anomalous heat flux is  
371 also on the order of 10% of the mean flux. Similar to the transient eddies, the anomalous heat  
372 flux is in the same (opposite) direction to that of the mean stationary eddy flux in the SH (NH).  
373 This suggests that stationary eddies are strengthened in the SH and weakened in the NH when  
374 the SAMHT is weaker.

375 Over mid-latitudes, eddy heat flux convergence (divergence) is primarily balanced by  
376 ascending (descending) motion. Similarly, momentum flux convergence (divergence) is balanced  
377 by westerly (easterly) acceleration. It was shown that 20 years after the weak SAMHT, heat  
378 fluxes from transient and stationary eddies converge (diverge) over the subtropical NH (SH).  
379 This indicates that atmospheric eddies work in the same direction as the anomalous MMC (Fig.  
380 7a) to produce anomalous ascending (descending) motion over the NH (SH) tropics, enhancing  
381 the north-to-south interhemispheric heat flux. The anomalous eddy heat flux poleward of 30°N  
382 (30°S) diverges (converges), producing subsidence (ascent) in the NH (SH). A more detailed  
383 discussion on the SAMHT role in modifying interhemispheric atmospheric transports will be  
384 presented in the discussion section.

385

## 386 **5. Modulation of the NH summer monsoons**

387 Results presented in earlier sections show that multi-decadal variation in SAMHT plays a  
388 key role in the global redistribution of heat and fresh water. It was also shown that it could  
389 provide about 15-20 years lead-time information on the atmospheric transport, including  
390 anomalous interhemispheric Hadley circulation. An important question that remains is whether  
391 such anomalous atmospheric heat and moisture transport modulates monsoonal circulation, and  
392 whether the SAMHT could be used as a potential predictor of decadal variability of the  
393 monsoons. To address this question, we will focus our attention on the NH summer monsoon  
394 season. A motivation for this question is that the NH summer climate is strongly influenced by  
395 tropical convection associated with the convectively-active monsoon phase. The monsoon is a  
396 robust component of seasonal variability. Its occurrence is highly dependent on the seasonal  
397 cycle of solar radiation, which gives rise to land-sea temperature contrast (e.g., Li and Yanai  
398 1996; Webster et al. 1998). Beyond seasonal variations, interannual variation of the monsoon is  
399 strongly influenced by larger-scale SST anomalies linked to El Niño Southern Oscillation  
400 (ENSO) (Wang et al. 2013). Therefore, monsoon simulations require the use of coupled models  
401 that capture interaction among all climate components. Ocean-atmosphere coupling may also  
402 introduce large errors due to uncertainties in the air-sea fluxes (Bollasina and Nigam 2009), in  
403 that small errors in one component of the climate system can be exacerbated by the other  
404 components. Sperber et al. (2013) analyzed the boreal summer Asian monsoon in the Coupled  
405 Model Intercomparison Project phase 5 and 3 (i.e., CMIP5 and CMIP3) models. They found an  
406 improvement in the simulation of monsoon circulation and precipitation from CMIP3 to CMIP5  
407 models, where the later models can reproduce some aspects (e.g., time-mean, annual cycle,  
408 intraseasonal, and interannual variability) of the monsoon.

409 Here, we will use precipitation and 850mb wind to characterize monsoon circulation in  
410 CESM1. The seasonality of global precipitation is well represented by CESM1 compared to the  
411 GPCP precipitation product (not shown). The largest seasonal range of precipitation is  
412 concentrated on a narrow equatorial band mostly over land, e.g., South Asia, west Africa, and  
413 Central America in the northern hemisphere, and Amazon basin, southeast Africa, and the  
414 maritime continent in the SH. Here, monsoon regions are identified by where the June-July-  
415 August-September (JJAS) minus December-January-February-March (DJFM) annual  
416 precipitation range is greater than 2mm/day and the local summer precipitation exceeds 55% of  
417 the total annual precipitation, following Wang et al. (2012). There are five monsoonal  
418 circulations in the NH. They are the Indian (INDM), East Asian (EAM), West Pacific (WPNM),  
419 North American (NAM), and North African (NAF) Monsoons. The INDM, EAM, and WPNM  
420 are often studied as one monsoon circulation, referred to as the Asian summer monsoon  
421 (Webster and Yang 1992). However, other studies have argued that the INDM and the EAM-  
422 WPNM systems owe to two distinct convective heat sources (Goswami et al. 1999; Wang and  
423 Fan 1999), where the former is forced by convection over the Arabian Sea and Bay of Bengal  
424 and the latter by convection over the South China Sea and the Philippines Sea, and that these two  
425 convective systems are poorly correlated. Consequently, this calls for the use of separate indices  
426 to study these monsoons.

427 Before analyzing the relationship between SAMHT and the monsoons, it is necessary to  
428 assess whether the model used here correctly simulates observed features of precipitation in the  
429 monsoon regions. CESM1 model reproduces the mean seasonal cycle for all monsoon regions,  
430 although with considerably weaker precipitation during the active phase (Fig. 9 left column).  
431 Precipitation associated with the EAM is significantly weaker throughout the year when

432 compared to the observed. The NAM and NAF monsoons are better represented in the model  
433 compared to the other monsoons.

434 The lag-lead relationship of SAMHT and NH monsoons is investigated here motivated by  
435 the zonally symmetric precipitation response in the tropics (Fig. 6c). Here, Spearman rank  
436 correlation is chosen over Pearson correlation as the former is a non-parametric test that does not  
437 make assumptions on the distribution of the data. It also does not make assumption of linear  
438 relationship between each variable. These two assumptions are especially troublesome for the  
439 analysis of precipitation over monsoon regions where precipitation could be non-normally  
440 distributed and its relationship with other climate indices (e.g., SAMHT) could be non-linear. In  
441 order to test the statistical significance of Spearman rank correlation, we rely on a non-  
442 parametric test known as Kendall-  $\tau$  test that measures the degree of dependence between two  
443 variables by comparing the number of concordant versus the number of discordant pairs.

444 Figure 9 (right-column) shows the lag-lead Spearman ranked correlation between  
445 SAMHT and NH monsoon index. The blue dashed lines depict the 95% significance level based  
446 on a non-parametric Kendall-  $\tau$  test. Negative lag indicates periods when SAMHT leads the NH  
447 monsoon index. Note that the SAMHT and NH monsoon indices are significantly anticorrelated  
448 when the SAMHT leads by 15-20 years. This is consistent with result described earlier in that the  
449 atmospheric response is preceded by SAMHT by 15-20 years. This negative correlation is  
450 indicative of a strengthening of the NH monsoon precipitation when SAMHT is weak. It also  
451 suggests that SAMHT could serve as a potential predictor for decadal variability of tropical NH  
452 precipitation.

453 Figure 10 (left column) shows the seasonality of precipitation and 850mb winds for the  
454 INDM, EAM, NAM, and NAF monsoon regions as measured by the difference in June-July-

455 August-September (JJAS) minus annual mean precipitation and winds. Multidecadal variability  
456 of monsoonal circulation and precipitation is analyzed as before by the composite difference  
457 corresponding to weak minus strong SAMHT at 20-year lead-time after the anomalous SAMHT.  
458 Fig. 10 (right column) depicts the composite difference of JJAS precipitation (shaded) and  
459 850mb rotational wind component for each monsoon region. Blue stipples indicate regions  
460 where precipitation differences are significant at 95% confidence level based on a non-  
461 parametric Kolmogorov-Smirnov test. This non-parametric test measures whether two samples  
462 (e.g., weak SAMHT period and strong SAMHT periods) have different distribution. Each region  
463 is discussed separately in bullets below:

464 I. Indian Monsoon (INDM, Findlater 1970; Yim et al. 2014). This monsoon circulation is  
465 associated with low-level southwesterlies and precipitation anomaly from the Arabian  
466 Sea to the Bay of Bengal (Fig. 10a). Multidecadal variability associated with weaker  
467 SAMHT is identified by enhanced precipitation over the Indian subcontinent and the  
468 Arabian Sea and less precipitation over the Indian Ocean (Fig. 10b). The circulation  
469 pattern shows enhanced southwesterly low-level jet associated with cyclonic circulation,  
470 which brings moisture convergence over India. This pattern reinforces the low-level  
471 southwesterly flow associated with the summer INDM.

472 II. East Asian Monsoon (EAM, Yim et al. 2014). This is a unique monsoon due to its higher  
473 latitude location. It presents itself as a dipole in precipitation (Fig. 10c). The composite  
474 difference shows a clear dipole in precipitation with positive (negative) anomaly over  
475 East China (East China Sea). Low-level anticyclonic circulation centered over southern  
476 Japan favors southwesterly flow towards east China and the Korean peninsula, bringing  
477 moisture from the Pacific Ocean. The decadal variability associated with SAMHT

478 presents a northward shift and intensification of this monsoon with respect to  
479 climatology.

480 III. North American Monsoon (NAM). Although the NAM is not as robust as the other  
481 monsoons mentioned above, it is an important component in seasonal precipitation over  
482 northwestern Mexico and the southwestern United States (Adams and Comrie 1997;  
483 Barlow et al. 1998; Cook and Seager 2013), accounting for over 70% of the annual total  
484 rainfall in these regions. The composite difference shows enhanced precipitation over  
485 western Mexico and the tropical eastern North Pacific Ocean (Fig. 10f). This is  
486 associated with moisture flux convergence over this region and consistent with  
487 strengthening of the summer monsoon (Fig. 10f).

488 IV. North African Monsoon (NAF, Yim et al. 2014). The composite difference shows  
489 enhanced precipitation and low-level westerly jet, bringing moisture from the Atlantic  
490 Ocean towards the Sahel region (Fig. 10h). This is consistent with the intensification of  
491 the westerlies and cross-equatorial flow from the Atlantic Ocean observed during the  
492 summer NAF monsoon (Fig. 10g).

493 In summary, all NH summer monsoons are enhanced during weaker a SAMHT. This is  
494 consistent with enhanced south-to-north hemisphere moisture transport by the anomalous Hadley  
495 circulation. Recall that there is weaker zonal flow due to anomalous southward eddy heat flux  
496 over the NH north of 25°N. This creates eddy heat flux convergence and ascending motion,  
497 therefore enhancing precipitation over these monsoon regions. These are important results  
498 suggesting that the SAMHT is a potential source of predictability, with about 20 years lead-time,  
499 of NH summer monsoon variability.

## 500 **6. Relative influence of the North and South Atlantic on Atmospheric Circulation**

501 Our analysis in previous sections indicates that decadal variability of SAMHT could  
502 modulate global atmospheric circulation and monsoons. However, since a similar link between  
503 NAMHT and global monsoons could potentially exist, it is important to understand the relative  
504 roles of SAMHT and NAMHT on modulating global monsoon variability. In other words, we  
505 need to identify whether SAMHT offers decadal predictability of global monsoons independent  
506 from that of NAMHT, which is a much more widely used index of AMOC and associated heat  
507 transport. Figure 11 depicts the anomalous interhemispheric atmospheric mass transport  
508 corresponding to a) weak minus strong SAMHT and b) weak minus strong NAMHT, similar to  
509 Fig. 5. Here, we are interested in those periods where the NAMHT and SAMHT lead the  
510 atmospheric transport (i.e., positive leads). There exists southward (i.e., negative) anomalous  
511 atmospheric heat transport about 18 years after the negative SAMHT anomaly (Fig. 11a, green  
512 line). This is also observed in the case of NAMHT, but for lead-time of about 25 years (Fig. 11b,  
513 green line).

514 There is difference in atmospheric response lead-times between NAMHT and SAMHT,  
515 which is depicted by diagonal magenta line in Fig. 11a and b, however, does not mean that  
516 SAMHT variability is independent from NAMHT. In fact, SAMHT variability is preceded by  
517 NAMHT variability, suggesting that the North Atlantic could provide more lead-time  
518 predictability than SAMHT. To further test, we attempted to separate the influence of the  
519 SAMHT and NAMHT on atmospheric transport by using conditional composite analysis and  
520 partial regression analysis. For this manuscript, we opt to show results from conditional  
521 composite analysis to be consistent with the rest of the paper, although both analyses give  
522 consistent results.

523 Figure 11c shows the annual mean (thin black) and composite difference of atmospheric

524 MMC as measured by the zonal mean 500mb atmospheric mass streamfunction. The composite  
525 difference is centered at lead times according to that of Fig. 11a and b (dashed green lines). The  
526 conditional composite for MMC (i.e., dependent variable) is built based on the state of the  
527 SAMHT and NAMHT (i.e., independent variables). Positive (negative) values indicate  
528 northward (southward) mass transport. Note that the influence of a weakening of SAMHT and  
529 NAMHT onto the MMC has similar amplitude. Also, the amplitude of the MMC anomaly is  
530 larger when both MHT indices are considered. This suggests that both the SAMHT and NAMHT  
531 and associated HC anomalies influence atmospheric circulation and transport. Although, the  
532 NAMHT leads the SAMHT negative HC anomaly in the South Atlantic associated with SAMHT  
533 divergence works in par with positive HC anomaly in the North Atlantic due to NAMHT  
534 convergence (see Fig. 4b), creating an interhemispheric asymmetry in energy balance. This  
535 asymmetry drives an anomalous Hadley circulation which transport heat from the NH to the SH  
536 (Fig. 11c green contour).

537         Several studies have suggested that the North Atlantic Oscillator (NAO) is a precursor of  
538 NAMHT variability, through wind stress and heat flux forcing in the high-latitudes oceanic  
539 convection regions (e.g., Eden and Willebrand 2001, Medhaug et al. 2012, Sun et al. 2015).  
540 Here, we address the relationship of NAMHT and SAMHT with the NAO. Fig. 12a show the  
541 lag-lead composite difference of NAO index for weak minus strong SAMHT (red) and NAMHT  
542 (blue). As suggested in Sun et al. (2015), the negative phase of the NAO precedes the weakening  
543 of NAMHT by about 15 years. This delayed effect is due to large inertia associated with slow  
544 oceanic processes. The reduced AMOC and NAMHT have a negative feedback in that the NAO  
545 shows a delayed response (i.e., positive phase) about 18 years after the weakening of the

546 NAMHT. However, the relationship between SAMHT and NAO is not robust. Thus, NAO does  
547 not give a predictability of SAMHT.

548

## 549 **7. Summary and Discussion**

550 This study tested the hypothesis whether low frequency (decadal) variability of the South  
551 Atlantic MOC and MHT influence decadal variability of climate events over the globe. A multi-  
552 century climate simulation based on a state-of-the-art coupled GCM was used as the basis for our  
553 analysis. Multi-decadal variability of the South Atlantic Ocean has been shown to play a key role  
554 in modulating atmospheric dynamics including the distribution of momentum, heat, and fresh  
555 water. For this reason, it is of great importance to the climate community to understand the role  
556 that the ocean plays and the physical mechanism behind this hypothesis. In this section, we  
557 highlight this mechanism, which was described in previous sections, using two summary  
558 schematic diagrams presented in Figs. 13 and 14.

559 The first diagram (Fig. 13) shows the transient evolution of MHT anomaly over the  
560 tropical Atlantic Ocean during weak minus strong SAMHT. Here, the gray shading indicates the  
561 anomalous negative MHT (i.e., weakening of the northward heat transport). The anomaly  
562 propagates from north-to-south (black arrows), where the anomaly at 30°N leads the anomaly at  
563 30°S by about 10-12 years with an approximate speed of ~600km/year. The largest amplitudes  
564 occur away from the equator. When the maximum anomaly arrives at 30°S (i.e., the location of  
565 our composite SAMHT or 0-year lag), there is MHT divergence between 30°S and the equator,  
566 highlighted by the dark-blue hatching and easily identified by the increased MHT southward  
567 away from the equator. The MHT divergence is balanced by negative heat content tendency,  
568 which results in negative heat content anomaly over the South Atlantic and negative SST

569 anomaly about 15-20 years later, shown by blue shading. The positive heat content anomaly in  
570 the NH is mostly due to MHT convergence approximately 10-12 years earlier. This creates an  
571 interhemispheric HC anomaly. The impact of these heat content anomalies on atmospheric  
572 circulation is discussed next.

573         The diagram in Fig. 14 shows the zonal mean atmospheric (top) and Atlantic Ocean  
574 (bottom) circulation. As discussed with respect to Fig. 13, weaker MHT (thick arrows on bottom  
575 panel) is associated with negative tendency in heat content over the subtropical South Atlantic  
576 (blue stipples at 0-year lag in Fig. 13). The heat content tendency is dominated by meridional  
577 MHT divergence (blue stipples in Fig. 13), producing a negative heat content anomaly  
578 approximately 15-20 years later. The negative (positive) heat content anomaly in the SH (NH)  
579 forces subsidence and anomalous Hadley circulation (gray oval and counterclockwise circulation  
580 in Fig. 14) that brings moisture from the SH to the NH (green arrow) and heat from the NH  
581 towards the SH (purple arrow). This anomalous interhemispheric atmospheric circulation is  
582 supported by a net gain in radiative fluxes at the top of the atmosphere (labeled  $R_{TOA}$ ) over the  
583 NH and net radiative loss over the SH represented by red and blue arrows, respectively. In  
584 addition, there is a net positive surface heat flux downward in the SH (blue arrows labeled heat  
585 flux). Atmospheric eddies, both transient and stationary, transport heat southward in both  
586 hemispheres (purple arrows) to balance the radiative fluxes. This produces eddy heat flux  
587 convergence around 15°N and divergence around 15°S (stipples), reinforcing the anomalous  
588 Hadley circulation. Poleward of 30° latitude, anomalous atmospheric eddies produce heat flux  
589 divergence (convergence) in the NH (SH), which causes sinking (rising) motion. This is  
590 consistent with a poleward (equatorward) displacement of the jet stream and mean storm track  
591 and enhanced (reduced) TOA radiation in the NH (SH). The poleward (equatorward)

592 displacement of the jet stream is a consequence of thermal wind balance from a reduced  
593 (enhanced) meridional temperature gradient over NH (SH) mid-latitudes. The poleward  
594 (equatorward) shift of the mean zonal jet in the NH (SH) causes eddy momentum flux  
595 convergence (divergence). This must be balanced by poleward (equatorward) flow at upper  
596 levels. This flow pattern supports a thermally indirect eddy driven circulation in both  
597 hemispheres (circulation labeled eddies in Fig. 14). This circulation brings anomalous ascent and  
598 more precipitation from 15°N-30°N, and descent and less precipitation poleward of 30°N. The  
599 opposite occurs in the SH, with descent and less precipitation from 30°S-15°S and ascent  
600 poleward of 30°S. In summary, the NH atmosphere behaves like the summer hemisphere,  
601 conversely, the SH behaves like the winter hemisphere, approximately 15-20 years after the  
602 anomalous negative SAMHT.

603         The proposed mechanism is in contrast with that of Sun et al. (2015) which suggests that  
604 the North Atlantic MOC can influence the SH mid-latitude zonal wind and precipitation. They  
605 found that strengthening of the North Atlantic MOC induces a subpolar interhemispheric SST  
606 seesaw pattern, with cold SST anomalies in high latitudes Southern Ocean. This leads to an  
607 enhanced meridional temperature gradient, increasing the zonal winds. The associated changes in  
608 the zonal wind could potentially influence SAMHT, explaining the lead-lag relationship of  
609 NAMHT and SAMHT. Although, we found that the geostrophic component of the SAMHT  
610 explains most of the low-frequency variance of the total SAMHT, whereas the Ekman (i.e.,  
611 wind-forced) component is comprised of higher frequencies. Further investigations on the  
612 contrasting mechanisms are necessary but beyond the scope of this study.

613

## 614 **8. Conclusion**

615           This is the first attempt to link the South Atlantic Overturning Circulation variability to  
616 weather and climate. The anomalous circulation pattern associated with SAMHT variability  
617 discussed throughout this paper has great implications for long-term climate variability over the  
618 whole globe. For example, it could bring drier and warmer summer conditions over North  
619 America and Europe. The results presented here suggest the possibility of decadal predictability  
620 of seasonal temperature and precipitation, more so for those regions affected by monsoonal  
621 circulation. It was shown that decadal modulation of the NH summer monsoon is tied to  
622 variability of the SAMHT. Intensification of the NH summer monsoon is through a northward  
623 shift and strengthening of the ITCZ when the SAMHT is weak via upper ocean heat content  
624 modification. This proposed mechanism utilizing the atmospheric energy budget to understand  
625 the ITCZ location is consistent with Kang et al. (2009) and Broccoli et al. (2006). Our hypothesis  
626 of a tropical control of the location of the ITCZ is in contrast with the possibility of a high-  
627 latitude control of the ITCZ location proposed in Frierson et al. (2013). The ITCZ in this study is  
628 shifted towards the warmer hemisphere, which is the NH, about 15-20 years after a weakening of  
629 the SAMHT.

630           The main objective here was to highlight the important role of the SAMHT in modifying  
631 atmospheric circulation. Most of the current literature places their effort in the North Atlantic.  
632 Here, we showed that the South Atlantic variability offers potential for added predictability of  
633 the climate system. Our argument that the SAMHT could modify the strength and location of the  
634 ITCZ has important implications, because the slowly-varying South Atlantic circulation could  
635 serve as potential predictor for decadal variability of the global monsoon system giving a lead-  
636 time of about 15-20 years from the anomalous MHT to its climate effects. Being this one of the  
637 first studies that investigates the role of the South Atlantic on climate and monsoons, further

638 efforts are necessary to confirm these results. For example, the processes that are responsible  
639 for the SAMHT variability are unclear. Is the SAMHT only a consequence of North Atlantic  
640 variability, or is it driven by independent local processes in the South Atlantic such as those  
641 mentioned in introduction? The relative roles of the North and South Atlantic MOC on the  
642 climate system needs further investigation. In future works, special emphasis will be given to  
643 high impact extreme weather events, such as droughts and heat waves. Also, the relative role of  
644 internal climate variability, like SAMHT, versus external forcing is an important question given  
645 the current climate projections (e.g., Lee et al. 2014). Results presented here highlight the need  
646 for continuous improvements in coupled models as well as the value of sustained ocean  
647 observational efforts, both necessary to improve our knowledge of the complex interaction  
648 between the South Atlantic MOC and global climate variability.

649

650 *Acknowledgement:* This research was carried out in part under the auspices of the Cooperative  
651 Institute of Marine and Atmospheric Studies, a cooperative institute of the University of Miami  
652 and the National Oceanic and Atmospheric Administration (NOAA), cooperative agreement  
653 NA10OAR4320143. This work was supported by NOAA Atlantic Oceanographic and  
654 Meteorological Laboratory and funded by Climate Observations Division of the Climate  
655 Program Office.

891

892 Figure 1. Meridional heat transport over the Atlantic Ocean (PetaWatts) from CESM1 model  
893 (black), gray shading represents one standard deviation. Also shown are estimated transports  
894 from NCEP (blue) and ECMWF reanalysis (red) from Trenberth et al. (2001). Direct estimates  
895 from the RAPID array at 26°N are shown in brown. Transport estimates from ARGO, XBTs, and  
896 altimetry observations at 34°S are shown by green color. The color shading and vertical bars  
897 depict one standard deviation calculated from annual average of MHT for each latitude.

898 Figure 2. 11-year running average of the SAMHT timeseries for a) total, b) Ekman, and c)  
899 geostrophic component for the 1100 model year analyzed. The total timeseries is defined as the  
900 meridional heat transport at 30°S after removing the seasonal cycle and linear trend. The Ekman  
901 component is estimated using monthly mean zonal wind stress from CESM1, whereas the  
902 geostrophic term is simply taken as the difference between the total and Ekman component. The  
903 red (blue) line fill contours indicate values greater (less) than one standard deviation.

904 Figure 3. The mean ocean meridional overturning streamfunction for the Atlantic (top) and  
905 global ocean (bottom), where positive streamfunction indicates clockwise flow. The mean

906 circulation is taken as the time mean, whereas the anomalous circulation is defined by the  
907 composite difference between weak minus strong SAMHT, shown by color shading.

908 Figure 4. a) Lead-lag composite difference of zonal mean Atlantic MHT with respect to weak  
909 minus strong SAMHT. b), c), d) and e) are similar to a) but for 700m Atlantic Ocean heat  
910 content (HC), heat content tendency, MHT divergence (positive for convergence), and net  
911 surface energy flux (positive downward into the ocean) respectively. Color shading indicates  
912 95% significance using a Kendall-tau test. The y-axis indicates time in years. Time progresses up  
913 the page with lag (lead) indicating SAMHT lags (leads), respectively.

914 Figure 5. Lead-lag composite difference of interhemispheric atmospheric circulation depicted as  
915 the vertically integrated mass transport about the equator for weak minus strong SAMHT. Here,  
916 the direction of interhemispheric atmospheric heat transport is proportional to the mass transport  
917 with northward (southward) labeled red (blue). Color shading indicates 95% significance using a  
918 student-T test. The y-axis indicates time in years. Time progresses up the page with lag (lead)  
919 indicating that SAMHT lags (leads), respectively.

920 Figure 6. Composite difference of a) 500mb air temperature, b) sea surface temperature, and c)  
921 precipitation corresponding to weak minus strong SAMHT at 20-year lead-time (i.e., 20 years  
922 after the anomalous SAMHT).

923 Figure 7. a) Time mean and zonal mean meridional circulation (MMC) of the atmosphere as  
924 measured by the mass streamfunction (contour) and composite difference (color) with respect to  
925 weak minus strong SAMHT at 20-year lead time (i.e., 20 years after the anomalous SAMHT, see  
926 Fig. 4). Panels b) and c) are similar to a) but for the meridional heat flux b), and meridional

927 moisture flux c), respectively. Mean northward heat and moisture flux are indicated by positive  
928 contours and positive shading depicts anomalous northward fluxes.

929 Figure 8. a) 500mb mean transient eddy heat flux (black) and composite difference (green)  
930 during weak minus strong SAMHT. Anomalous heat flux convergence (divergence) is  
931 highlighted by red (blue) regions on the composite difference line. b) Stationary eddy heat flux  
932 (black contour) and composite difference (color shading) during weak minus strong SAMHT.  
933 Similar to Fig. 7, the composite difference is analyzed 20 years after the anomalous SAMHT.

934 Figure 9. (left column) Seasonality of precipitation of the four monsoon regions (i.e., Indian  
935 (INDM), East Asian (EAM), North American (NAM), and North African Monsoon (NAF)) from  
936 GPCC (blue) and CESM1 (red). Error bars indicate the 99% confidence level. (right-column)  
937 Lag-lead Spearman ranked correlation between SAMHT and NH monsoon index. The blue  
938 dashed lines depict the 95% significance level based on a non-parametric Kendall- $\tau$  test.  
939 Negative lag indicates periods when SAMHT leads the NH monsoon index. Periods with  
940 significant correlation are shaded blue.

941 Figure 10. (left column) Seasonality of precipitation and 850mb winds for the monsoon regions  
942 (i.e., Indian (INDM), East Asian (EAM), North American (NAM), and North African Monsoon  
943 (NAF) as measured by the difference between June-July-August-September (JJAS) minus annual  
944 mean precipitation and winds. (right-column) The composite difference of JJAS precipitation  
945 (shaded) and 850mb wind for each monsoon region with respect to weak minus strong SAMHT  
946 at lead-time 20 years after the anomalous SAMHT. Blue stipples indicates regions where  
947 precipitation differences are significant at 95% confidence level based on a non-parametric  
948 Kolmogorov-Smirnov test.

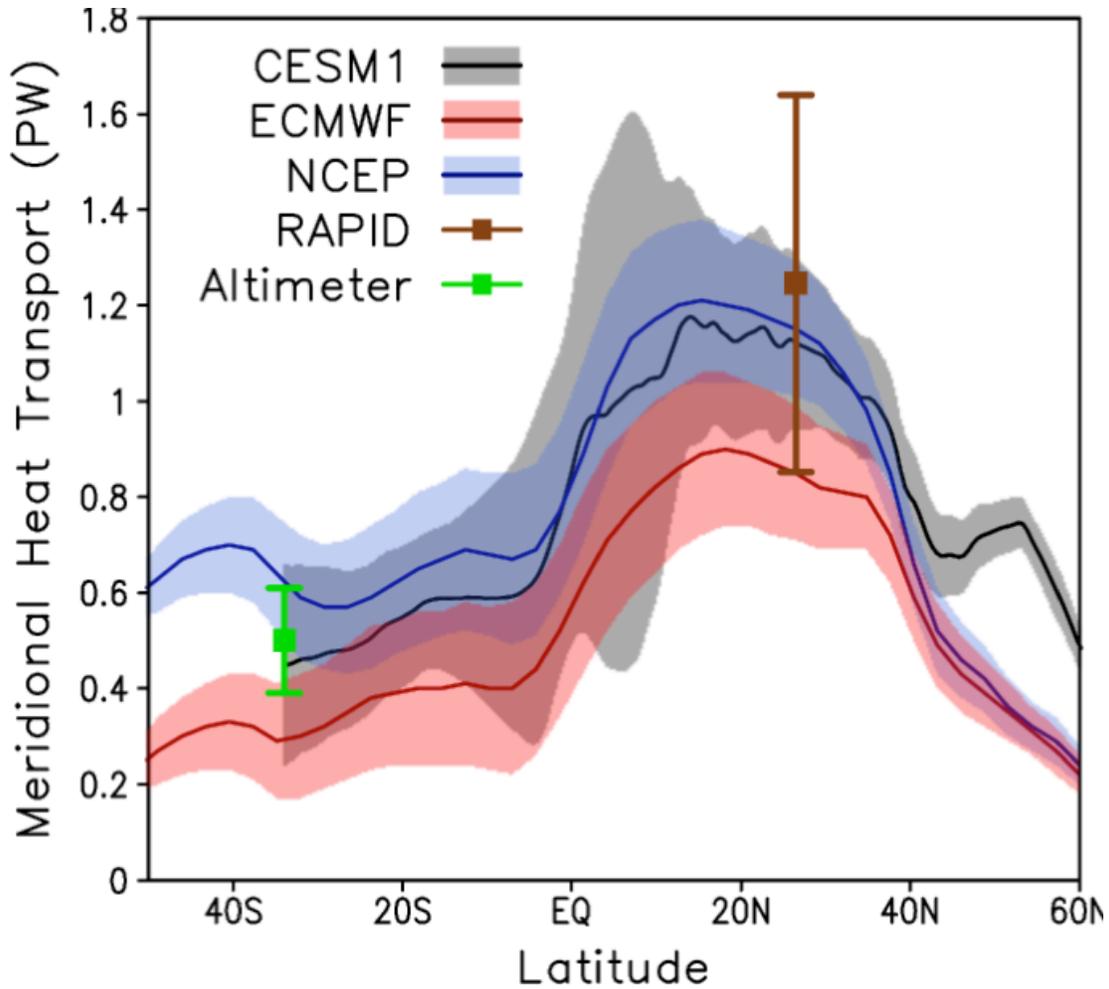

949 Figure 11. Anomalous interhemispheric atmospheric mass transport corresponding to a) weak  
950 minus strong SAMHT and b) weak minus strong NAMHT, similar to Fig. 5. The diagonal  
951 magenta line between panels a) and b) highlights the fact that NAMHT leads SAMHT. c) Annual  
952 mean (thin black) and composite difference of atmospheric mean meridional circulation (MMC)  
953 as measured by the zonal mean 500mb atmospheric mass streamfunction. The composite  
954 difference is centered at lead times according to that of a) and b) (dashed green lines). The  
955 conditional composite for MMC (i.e., dependent variable) is built based on the state of the  
956 SAMHT and NAMHT (i.e., independent variables). The green contour here includes the  
957 relationship between the MMC with both, SAMHT and NAMHT. Red contour depicts the  
958 relationship between NAMHT and the MMC excluding the influence of SAMHT (i.e., neutral  
959 SAMHT periods based on terciles). Similarly, blue contour shows the relationship between  
960 SAMHT and the MMC excluding the influence of NAMHT (i.e., neutral NAMHT periods based  
961 on terciles). Positive (negative) values indicate northward (southward) mass transport.

962 Figure 12. a) Lead-lag composite difference of North Atlantic Oscillator (NAO) index for weak  
963 minus strong SAMHT (red) and weak minus strong NAMHT (blue). The y-axis indicates time in  
964 years. Time progresses up the page with lag (lead) indicating the ocean MHT lags (leads),  
965 respectively. b) 500mb geopotential height anomaly associated with the positive phase of the  
966 NAO.

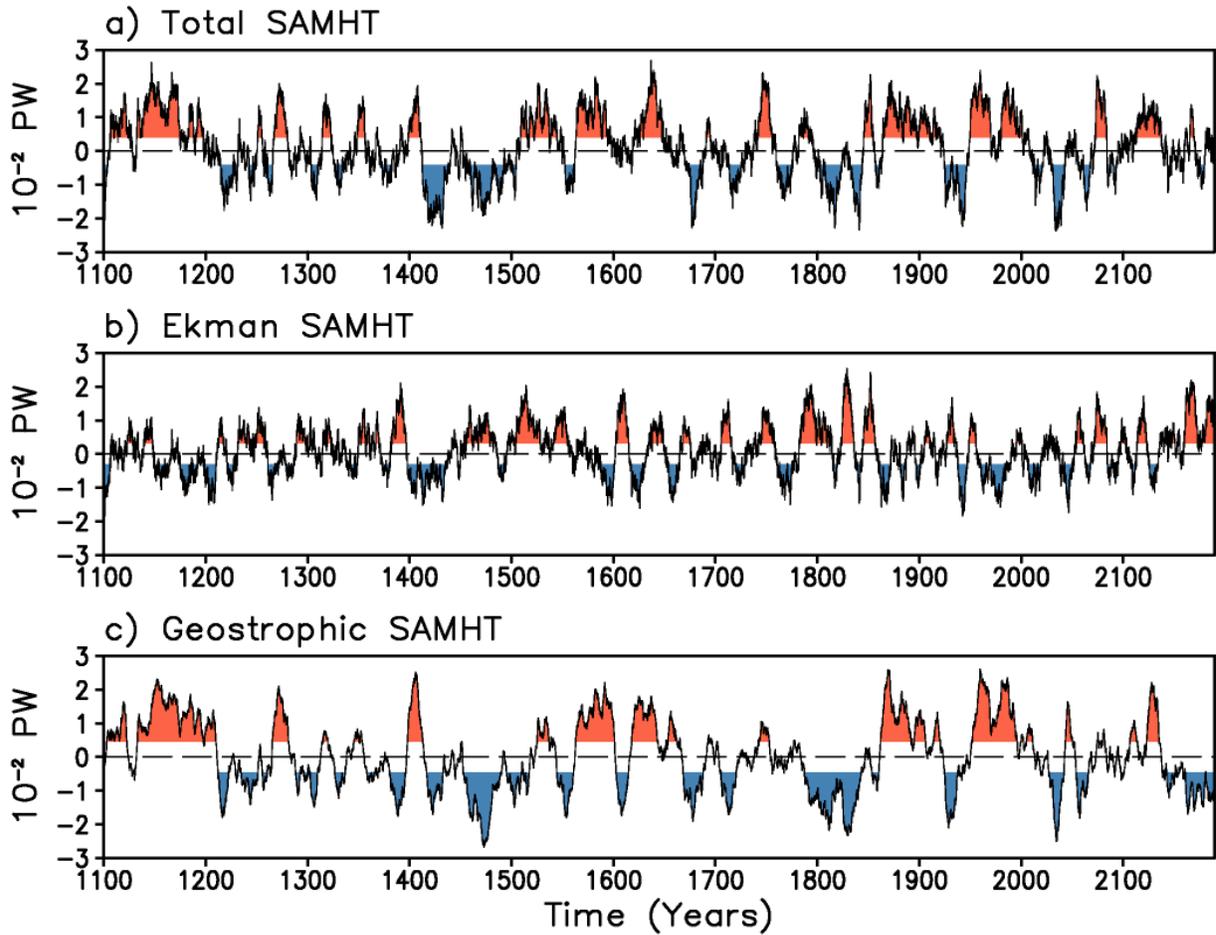

967 Figure 13. **Transient evolution of MHT anomaly over the tropical Atlantic Ocean during**  
968 **weak minus strong SAMHT.** Gray shading indicates the anomalous negative MHT (i.e.,  
969 weakening of the northward heat transport). The anomaly propagates from north to south (black  
970 arrows) at about 600km/year. The dark-red hatched region indicates meridional heat transport  
971 convergence and positive heat content tendency north of the equator 10-15 years prior to the

972 weak minus strong SAMHT, whereas the dark-blue hatched region indicates meridional heat  
973 transport divergence and negative heat content tendency south of the equator near 0-lag with  
974 respect to weak minus strong SAMHT. Blue (red) shading depicts negative (positive) heat  
975 content. The y-axis indicates time in years. Time progresses up the page, with lag (lead)  
976 indicating SAMHT lags (leads), respectively. Anomalous heat content occurs about 15-20 years  
977 after the anomalous heat content tendency and heat transport divergence in both hemispheres.

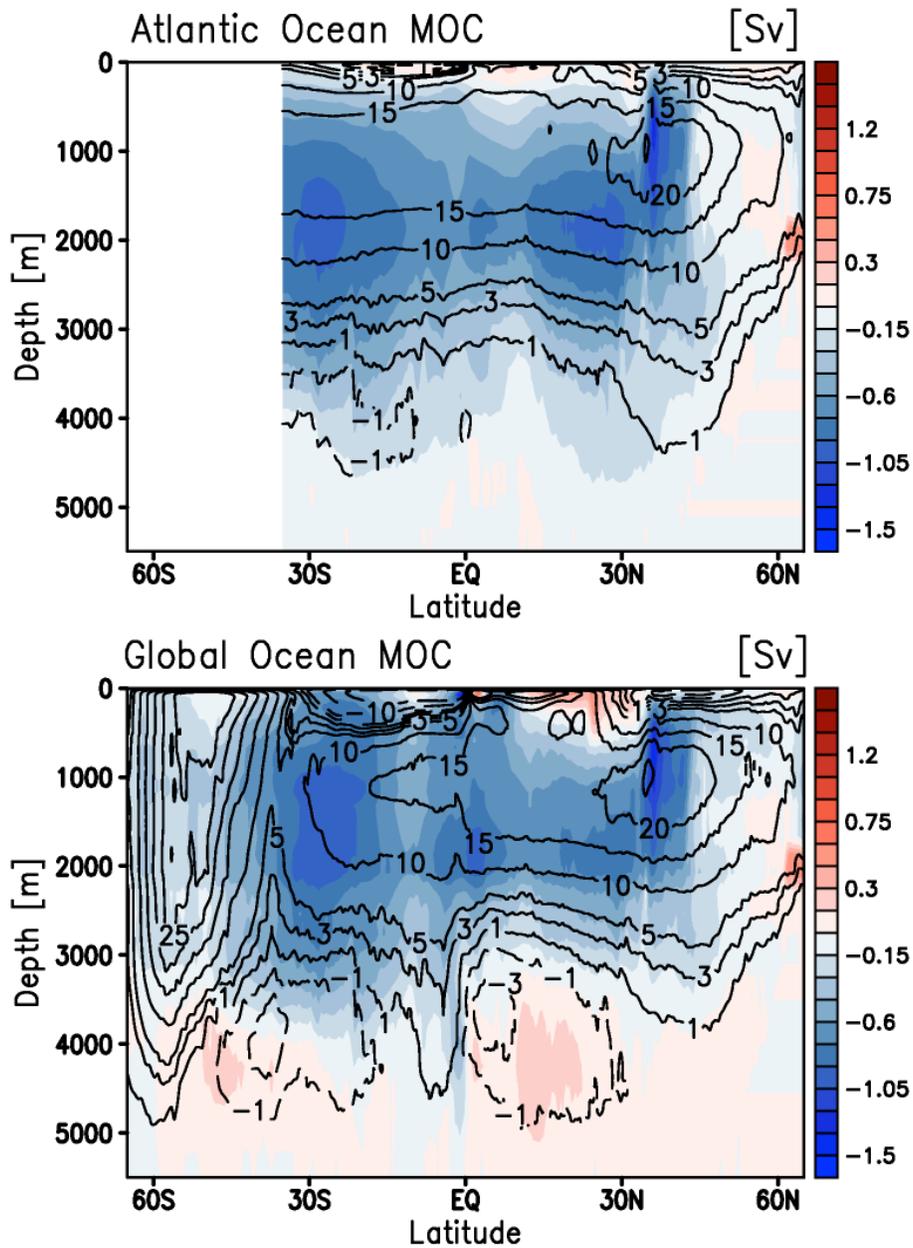

978 **Figure 14. Schematic diagram of the role of weaker-than-normal MHT in the anomalous**  
979 **atmospheric circulation at 15-20 years lead-time.** Weakened MHT is shown by thick black  
980 arrows on the bottom panel. Negative (positive) tendency in heat content is labeled by dark-blue  
981 (red) hatching. There is negative (positive) heat content in the SH (NH) about 15-20 years after  
982 the heat transport anomaly labeled here by blue (red) rectangle. Anomalous Hadley circulation is  
983 labeled by gray oval and counterclockwise circulation. Moisture and heat fluxes are shown by  
984 green and purple arrows, respectively. The TOA and surface radiative fluxes are shown by thick  
985 red and blue arrows. Purple arrows depict atmospheric eddy heat transports. Eddy forced vertical  
986 motion is shown by red and blue stipples. See discussion in main text for more details.

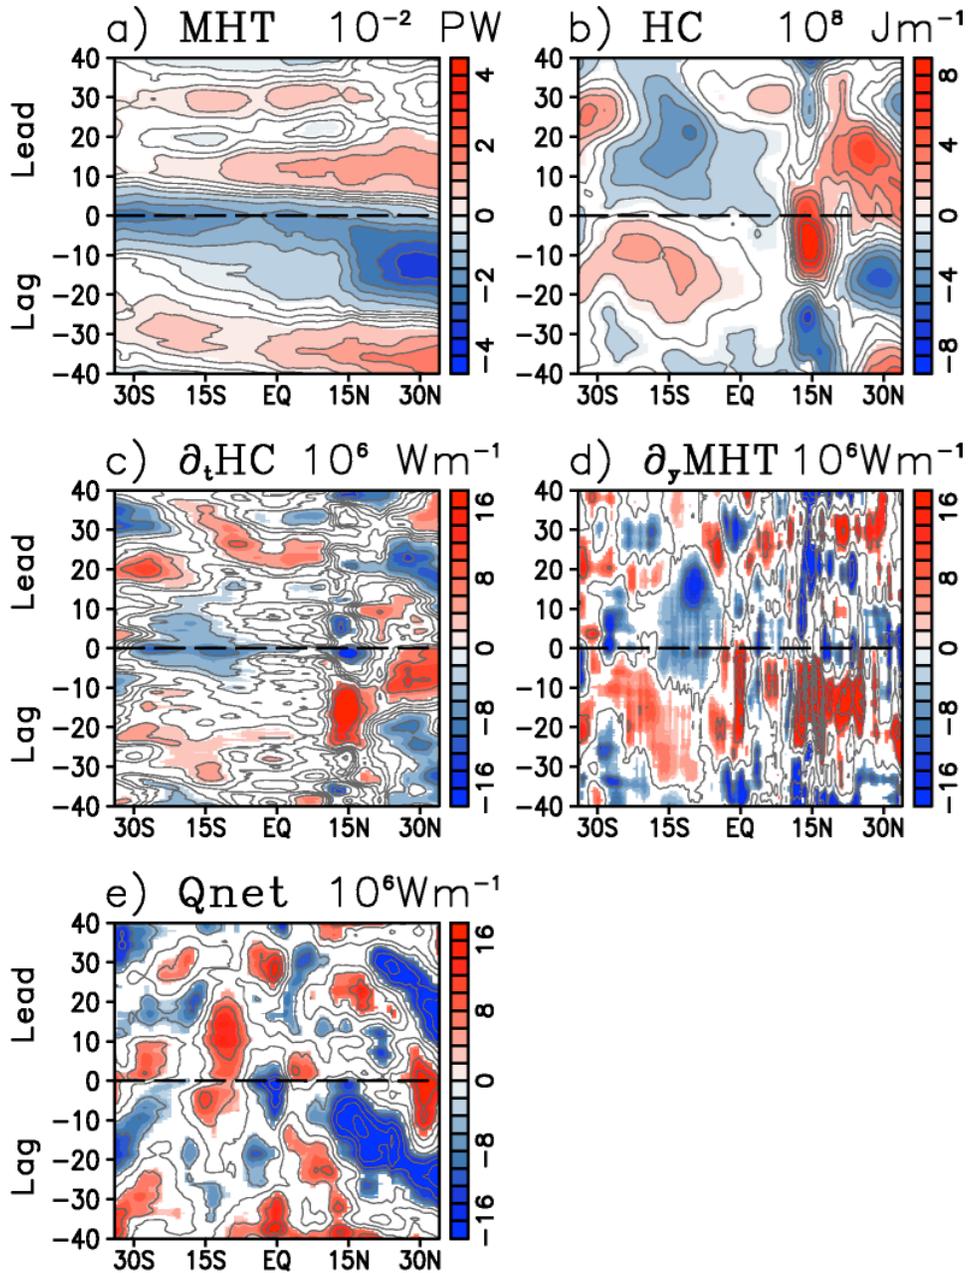

987  
 988  
 989 Figure 1. Meridional heat transport over the Atlantic Ocean (PetaWatts) from CESM1 model  
 990 (black), gray shading represents one standard deviation. Also shown are estimated transports  
 991 from NCEP (blue) and ECMWF reanalysis (red) from Trenberth et al. (2001). Direct estimates  
 992 from the RAPID array at 26°N are shown in brown. Transport estimates from ARGO, XBTs, and  
 993 altimetry observations at 34°S are shown by green color. The color shading and vertical bars  
 994 depict one standard deviation calculated from annual average of MHT for each latitude.

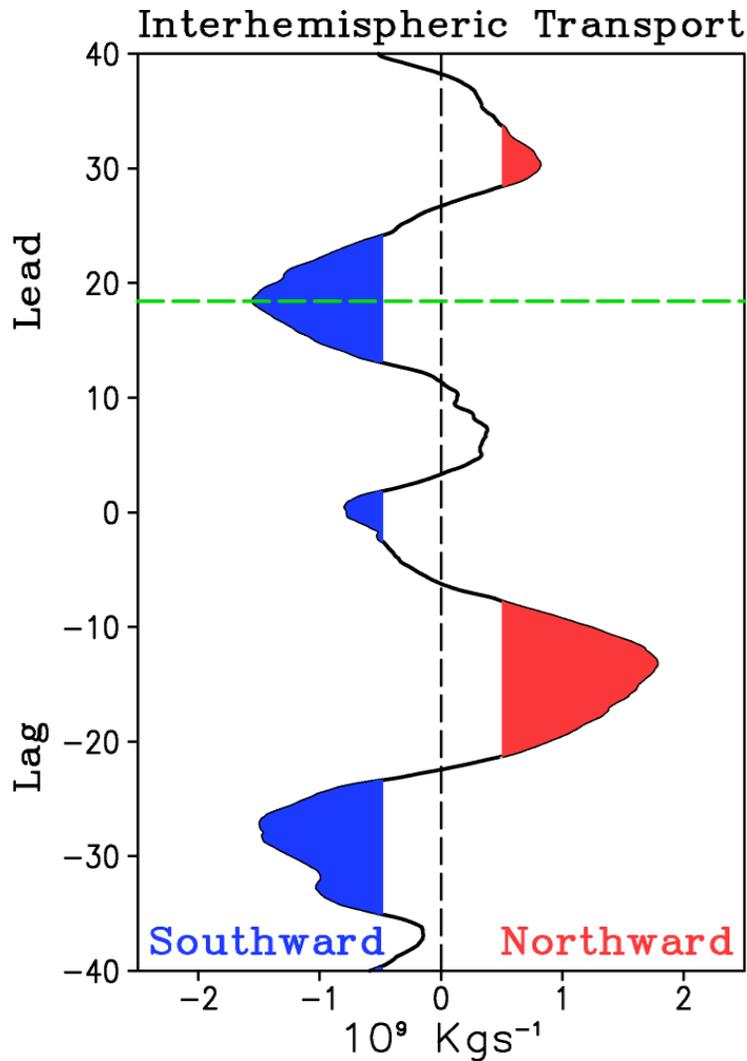

995  
 996 Figure 2. 11-year running average of the SAMHT timeseries for a) total, b) Ekman, and c)  
 997 geostrophic component for the 1100 model year analyzed. The total timeseries is defined as the  
 998 meridional heat transport at 30°S after removing the seasonal cycle and linear trend. The Ekman  
 999 component is estimated using monthly mean zonal wind stress from CESM1, whereas the  
 1000 geostrophic term is simply taken as the difference between the total and Ekman component. The  
 1001 red (blue) line fill contours indicate values greater (less) than one standard deviation.

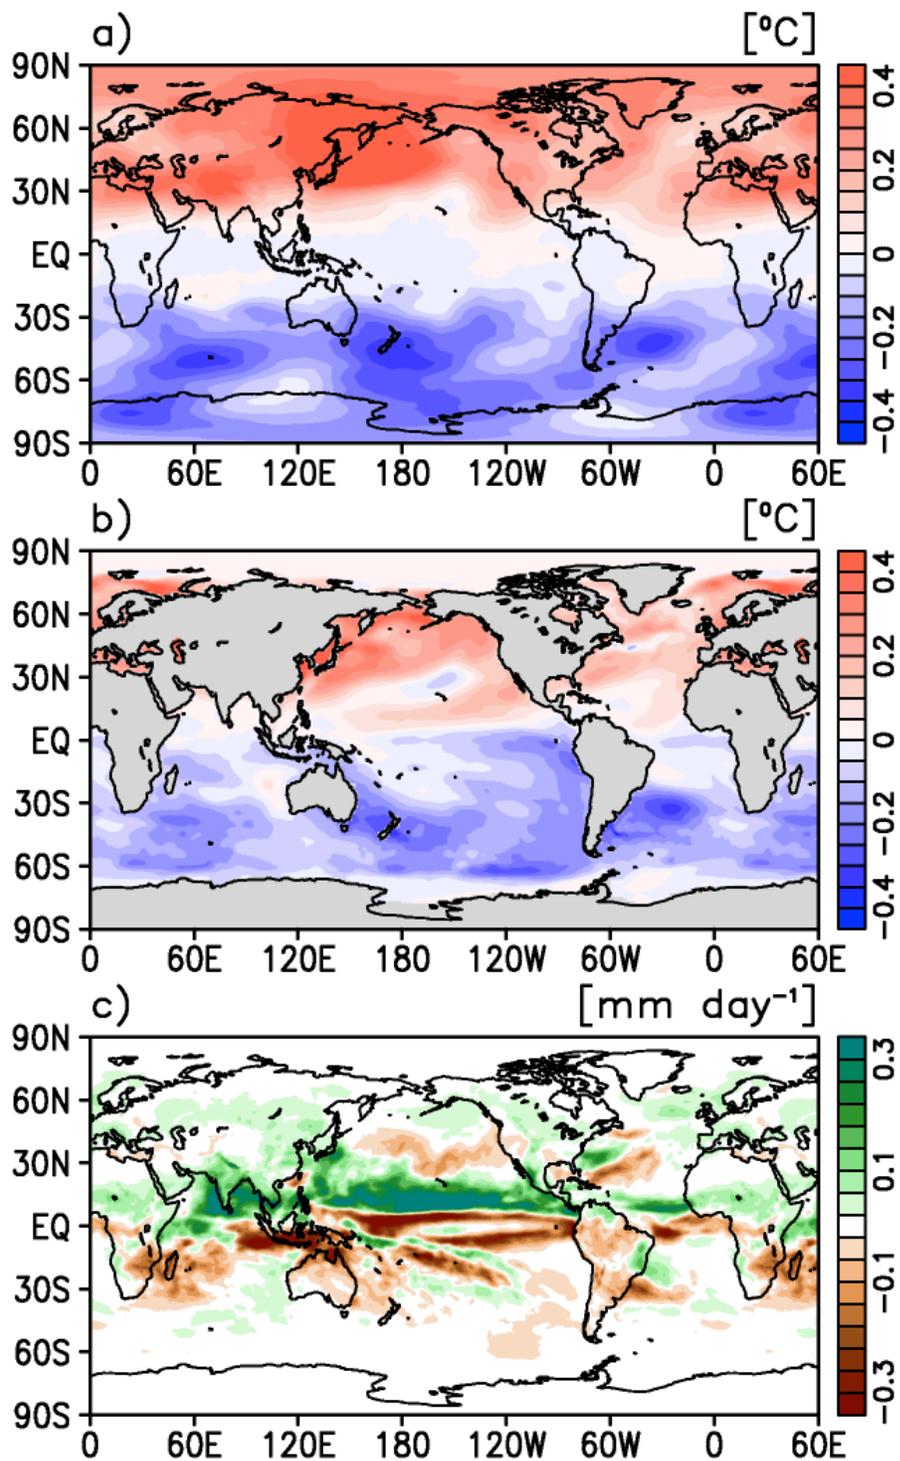

1002  
 1003 Figure 3. The mean ocean meridional overturning streamfunction for the Atlantic (top) and  
 1004 global ocean (bottom), where positive streamfunction indicates clockwise flow. The mean  
 1005 circulation is taken as the time mean, whereas the anomalous circulation is defined by the  
 1006 composite difference between weak minus strong SAMHT, shown by color shading.

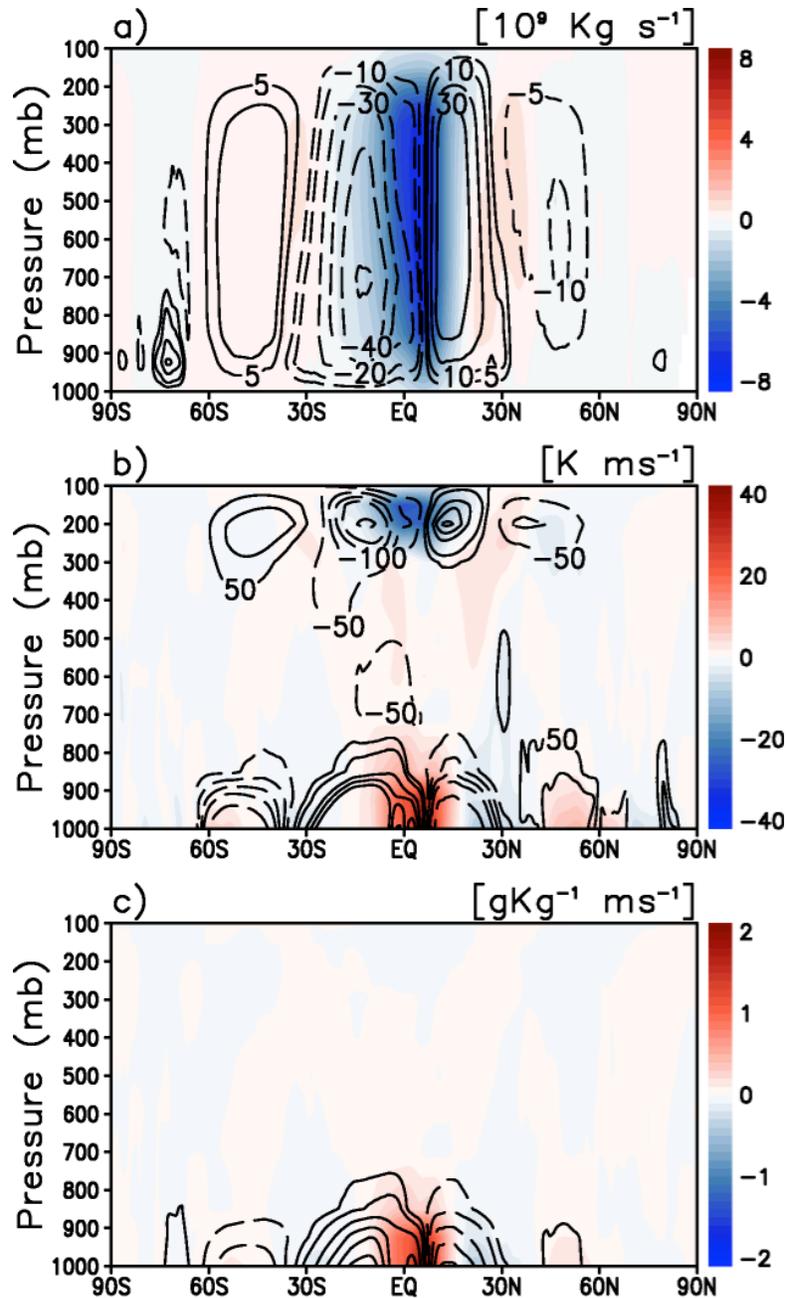

1007  
 1008 Figure 4. a) Lead-lag composite difference of zonal mean Atlantic MHT with respect to weak  
 1009 minus strong SAMHT. b), c), d) and e) are similar to a) but for 700m Atlantic Ocean heat  
 1010 content (HC), heat content tendency, MHT divergence (positive for convergence), and net  
 1011 surface energy flux (positive downward into the ocean) respectively. Color shading indicates  
 1012 95% significance using a Kendall-tau test. The y-axis indicates time in years. Time progresses up  
 1013 the page with lag (lead) indicating SAMHT lags (leads), respectively.

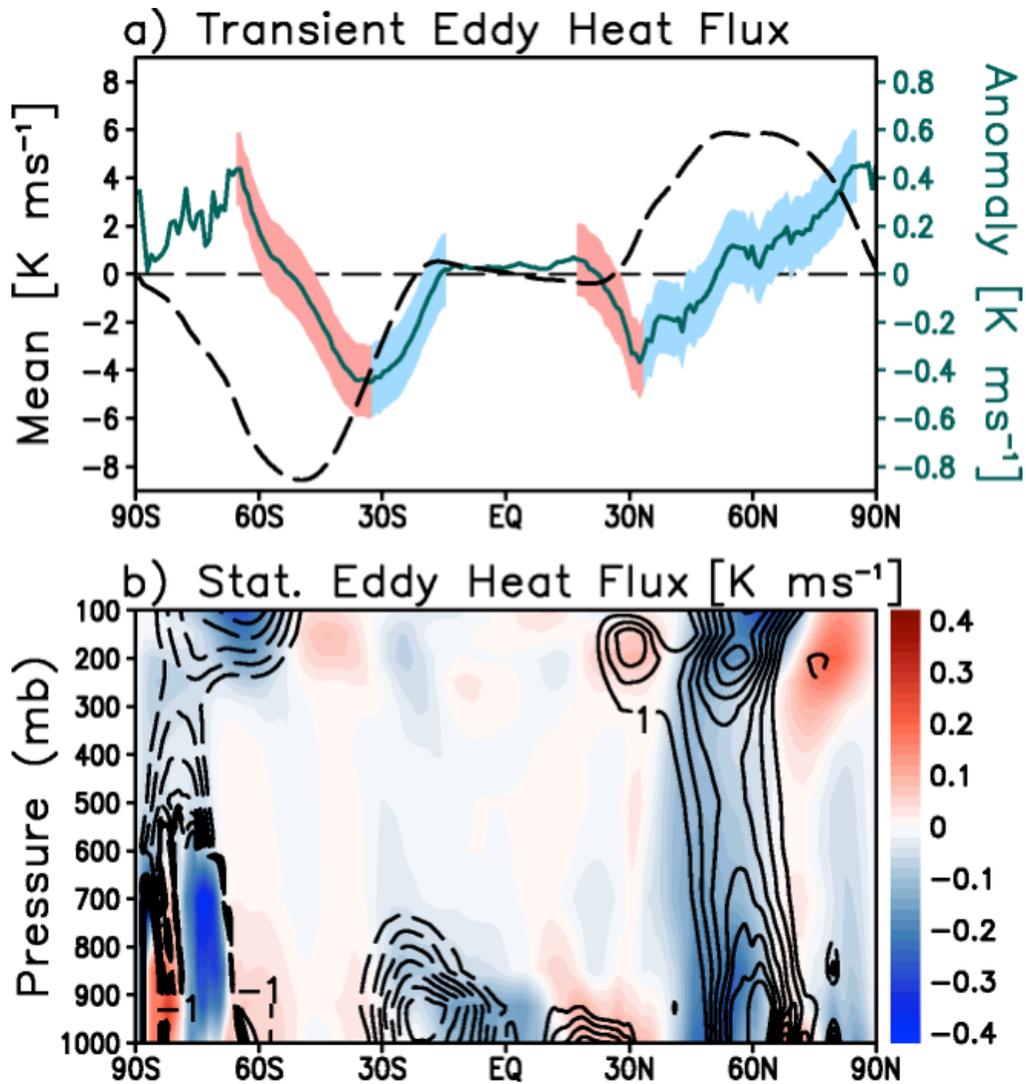

1014  
 1015 Figure 5. Lead-lag composite difference of interhemispheric atmospheric circulation depicted as  
 1016 the vertically integrated mass transport about the equator for weak minus strong SAMHT. Here,  
 1017 the direction of interhemispheric atmospheric heat transport is proportional to the mass transport  
 1018 with northward (southward) labeled red (blue). Color shading indicates 95% significance using a  
 1019 student-T test. The y-axis indicates time in years. Time progresses up the page with lag (lead)  
 1020 indicating that SAMHT lags (leads), respectively.

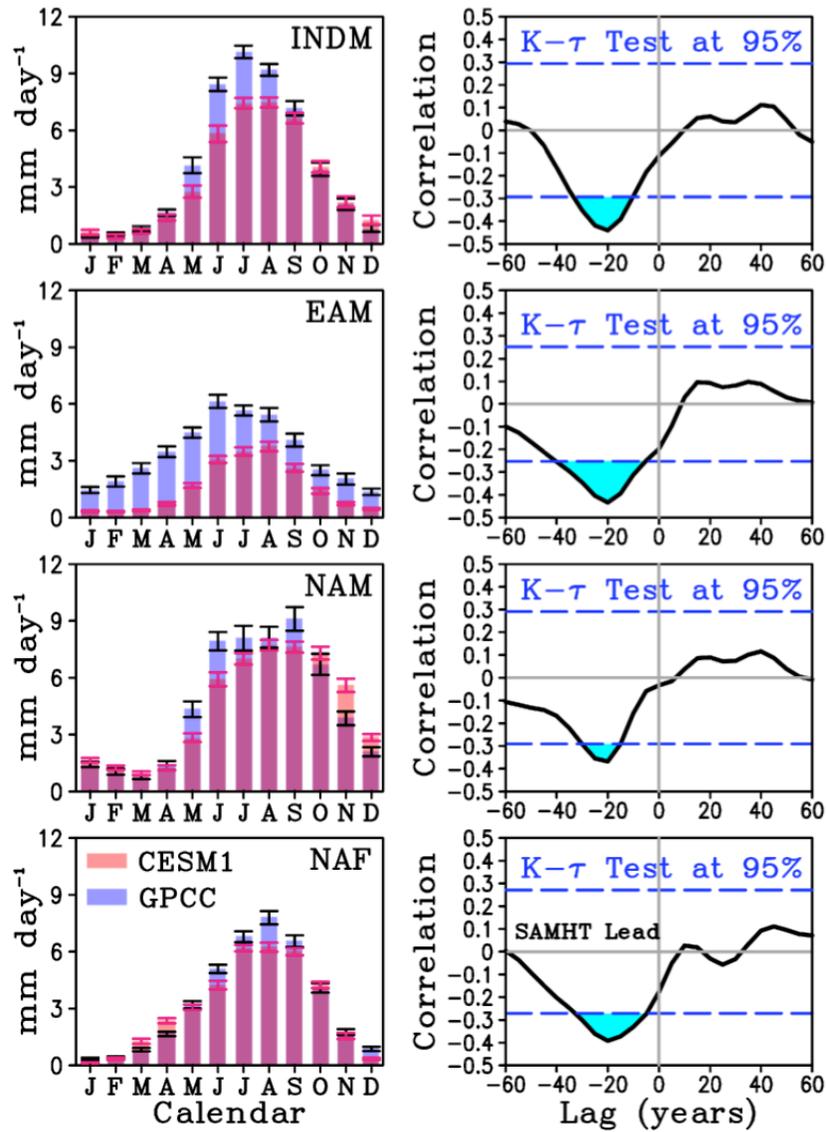

1021  
 1022 Figure 6. Composite difference of a) 500mb air temperature, b) sea surface temperature, and c)  
 1023 precipitation corresponding to weak minus strong SAMHT at 20-year lead-time (i.e., 20 years  
 1024 after the anomalous SAMHT).

1025  
 1026 Figure 7. a) Time mean and zonal mean meridional circulation (MMC) of the atmosphere as  
 1027 measured by the mass streamfunction (contour) and composite difference (color) with respect to  
 1028 weak minus strong SAMHT at 20-year lead time (i.e., 20 years after the anomalous SAMHT, see  
 1029 Fig. 4). Panels b) and c) are similar to a) but for the meridional heat flux b), and meridional  
 1030 moisture flux c), respectively. Mean northward heat and moisture flux are indicated by positive  
 1031 contours and positive shading depicts anomalous northward fluxes.

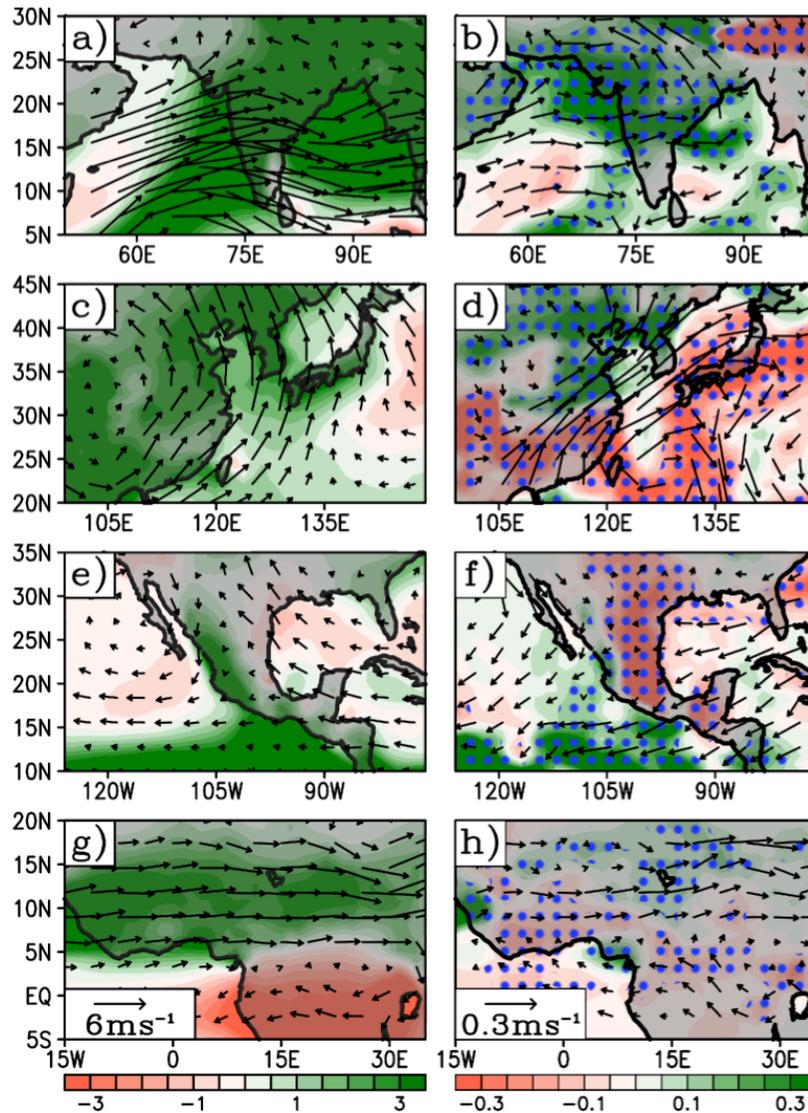

1032  
 1033 Figure 8. a) 500mb mean transient eddy heat flux (black) and composite difference (green)  
 1034 during weak minus strong SAMHT. Anomalous heat flux convergence (divergence) is  
 1035 highlighted by red (blue) regions on the composite difference line. b) Stationary eddy heat flux  
 1036 (black contour) and composite difference (color shading) during weak minus strong SAMHT.  
 1037 Similar to Fig. 7, the composite difference is analyzed 20 years after the anomalous SAMHT.

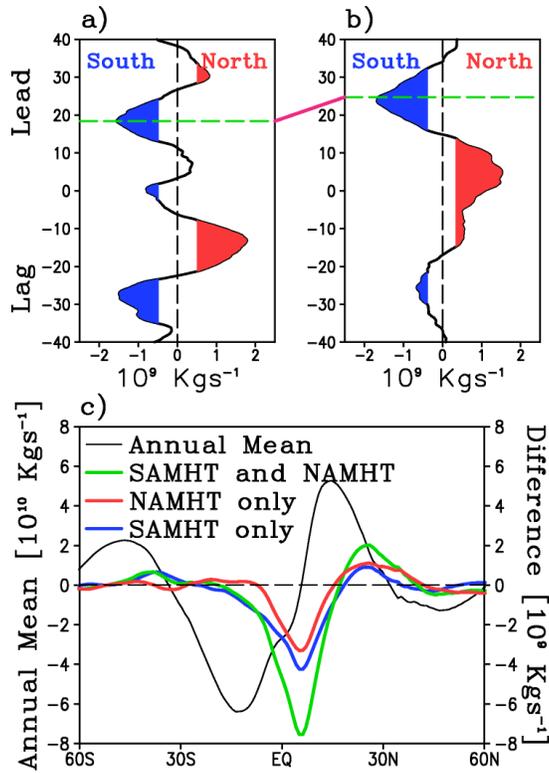

1038

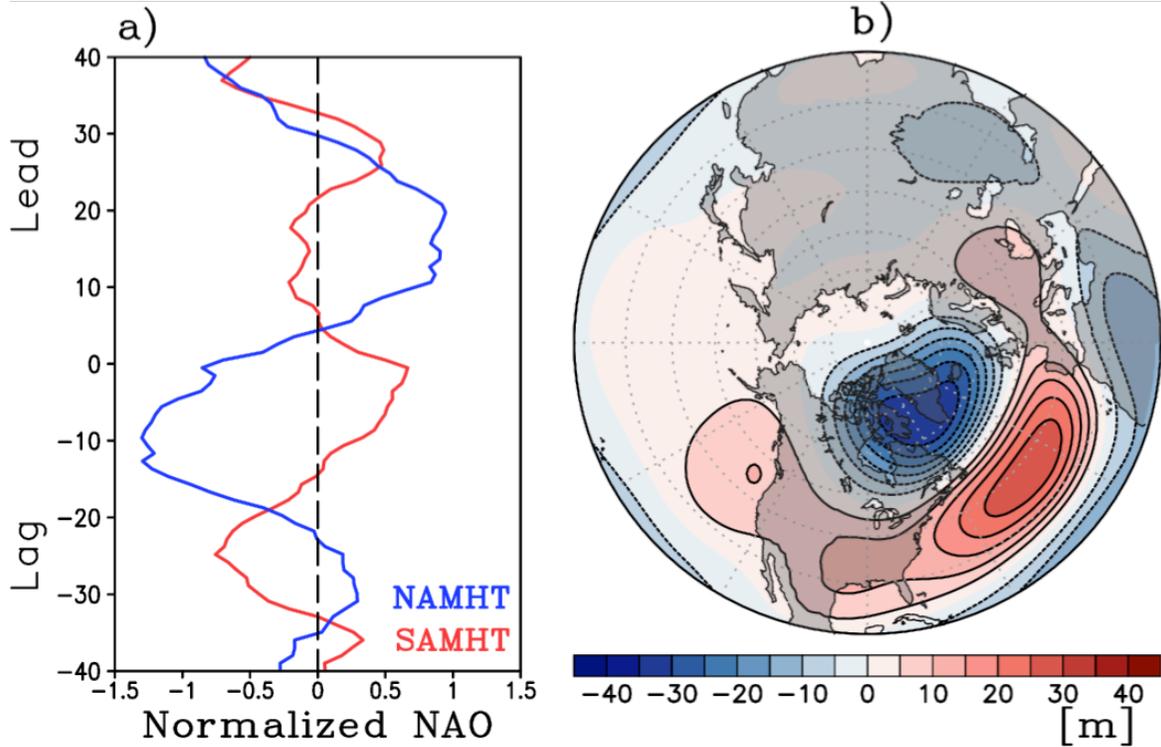

1039 Figure 9. (left column) Seasonality of precipitation of the four monsoon regions (i.e., Indian  
 1040 (INDM), East Asian (EAM), North American (NAM), and North African Monsoon (NAF)) from  
 1041 GPCP (blue) and CESM1 (red). Error bars indicate the 99% confidence level. (right-column)  
 1042 Lag-lead Spearman ranked correlation between SAMHT and NH monsoon index. The blue  
 1043 dashed lines depict the 95% significance level based on a non-parametric Kendall- $\tau$  test.  
 1044 Negative lag indicates periods when SAMHT leads the NH monsoon index. Periods with  
 1045 significant correlation are shaded blue.

1046  
 1047 Figure 10. (left column) Seasonality of precipitation and 850mb winds for the monsoon regions  
 1048 (i.e., Indian (INDM), East Asian (EAM), North American (NAM), and North African Monsoon  
 1049 (NAF) as measured by the difference between June-July-August-September (JJAS) minus annual  
 1050 mean precipitation and winds. (right-column) The composite difference of JJAS precipitation  
 1051 (shaded) and 850mb wind for each monsoon region with respect to weak minus strong SAMHT  
 1052 at lead-time 20 years after the anomalous SAMHT. Blue stipples indicates regions where  
 1053 precipitation differences are significant at 95% confidence level based on a non-parametric  
 1054 Kolmogorov-Smirnov test

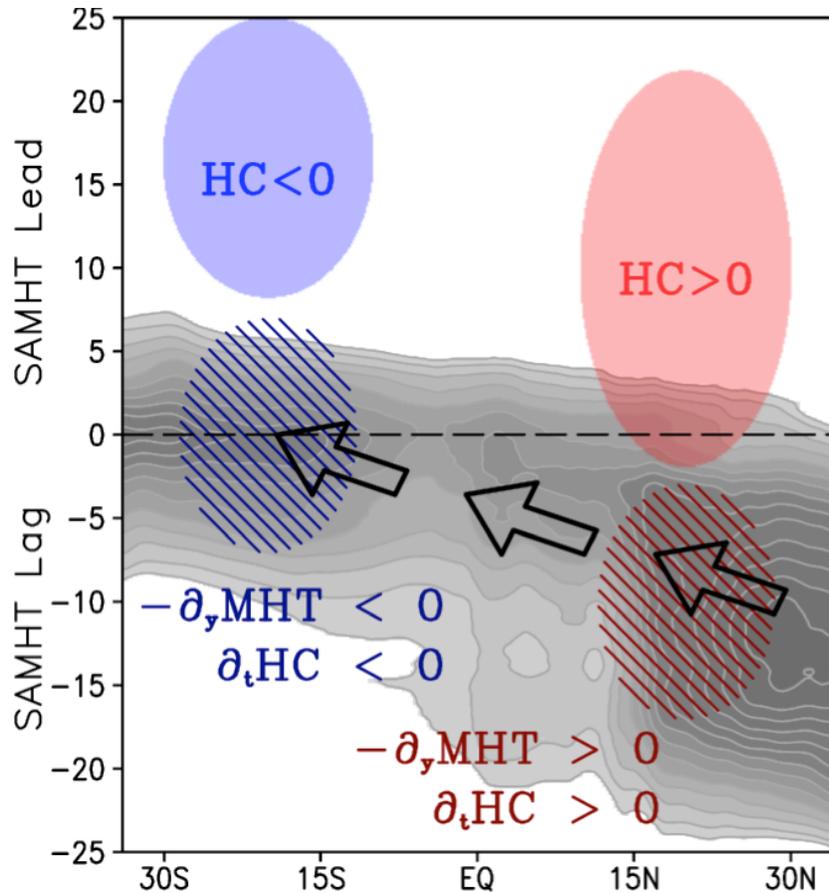

1055  
 1056 Figure 11. Anomalous interhemispheric atmospheric mass transport corresponding to a) weak  
 1057 minus strong SAMHT and b) weak minus strong NAMHT, similar to Fig. 5. The diagonal  
 1058 magenta line between panels a) and b) highlights the fact that NAMHT leads SAMHT. c) Annual  
 1059 mean (thin black) and composite difference of atmospheric mean meridional circulation (MMC)  
 1060 as measured by the zonal mean 500mb atmospheric mass streamfunction. The composite  
 1061 difference is centered at lead times according to that of a) and b) (dashed green lines). The  
 1062 conditional composite for MMC (i.e., dependent variable) is built based on the state of the  
 1063 SAMHT and NAMHT (i.e., independent variables). The green contour here includes the  
 1064 relationship between the MMC with both, SAMHT and NAMHT. Red contour depicts the  
 1065 relationship between NAMHT and the MMC excluding the influence of SAMHT (i.e., neutral  
 1066 SAMHT periods based on terciles). Similarly, blue contour shows the relationship between  
 1067 SAMHT and the MMC excluding the influence of NAMHT (i.e., neutral NAMHT periods based  
 1068 on terciles). Positive (negative) values indicate northward (southward) mass transport.

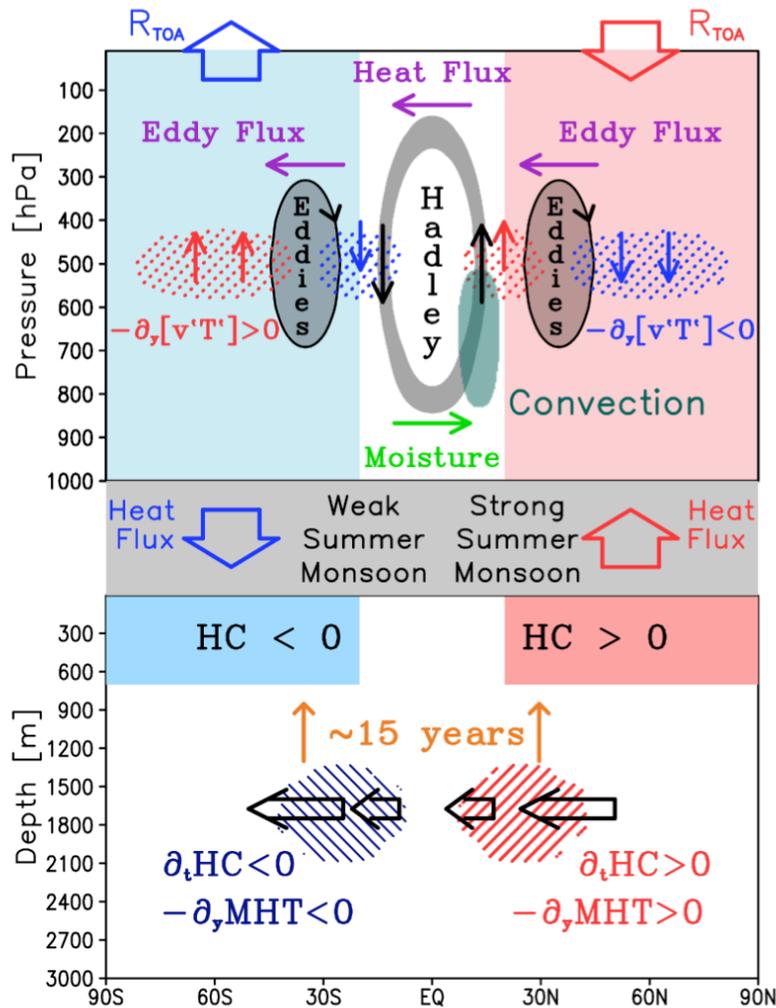

1069

1070 Figure 12. a) Lead-lag composite difference of North Atlantic Oscillator (NAO) index for weak  
 1071 minus strong SAMHT (red) and weak minus strong NAMHT (blue). The y-axis indicates time in  
 1072 years. Time progresses up the page with lag (lead) indicating the ocean MHT lags (leads),  
 1073 respectively. b) 500mb geopotential height anomaly associated with the positive phase of the  
 1074 NAO.

1075  
 1076 Figure 13. **Transient evolution of MHT anomaly over the tropical Atlantic Ocean during**  
 1077 **weak minus strong SAMHT.** Gray shading indicates the anomalous negative MHT (i.e.,  
 1078 weakening of the northward heat transport). The anomaly propagates from north to south (black  
 1079 arrows) at about 600km/year. The dark-red hatched region indicates meridional heat transport  
 1080 convergence and positive heat content tendency north of the equator 10-15 years prior to the  
 1081 weak minus strong SAMHT, whereas the dark-blue hatched region indicates meridional heat  
 1082 transport divergence and negative heat content tendency south of the equator near 0-lag with  
 1083 respect to weak minus strong SAMHT. Blue (red) shading depicts negative (positive) heat  
 1084 content. The y-axis indicates time in years. Time progresses up the page, with lag (lead)  
 1085 indicating SAMHT lags (leads), respectively. Anomalous heat content occurs about 15-20 years  
 1086 after the anomalous heat content tendency and heat transport divergence in both hemispheres.

1087  
 1088 Figure 14. **Schematic diagram of the role of weaker-than-normal MHT in the anomalous**  
 1089 **atmospheric circulation at 15-20 years lead-time.** Weakened MHT is shown by thick black  
 1090 arrows on the bottom panel. Negative (positive) tendency in heat content is labeled by dark-blue  
 1091 (red) hatching. There is negative (positive) heat content in the SH (NH) about 15-20 years after  
 1092 the heat transport anomaly labeled here by blue (red) rectangle. Anomalous Hadley circulation is  
 1093 labeled by gray oval and counterclockwise circulation. Moisture and heat fluxes are shown by  
 1094 green and purple arrows, respectively. The TOA and surface radiative fluxes are shown by thick  
 1095 red and blue arrows. Purple arrows depict atmospheric eddy heat transports. Eddy forced vertical  
 1096 motion is shown by red and blue stipples. See discussion in main text for more details.
